The first elementary matter particle to be identified was the spin-1/2 electron (weighing about 1/2 MeV), followed by the unstable muon (weighing about 100 MeV) that was first detected in COSMIC RAYS. These were shown each to have an associated neutrino, the electron neutrino being produced in weak β decay and the muon neutrino being produced either in association with a muon or in muon decays. These particles do not have strong nuclear interactions, only weak and (in the case of the electron and muon, which are charged particles) electromagnetism, and are called LEPTONS. A third type of charged lepton (the τ weighing about 1.78 GeV) was discovered in accelerator experiments at SLAC in 1975 and is also believed to have its own associated neutrino. Accelerator data have established upper limits on the possible masses of the neutrinos, which are much less than those of the corresponding charged leptons.

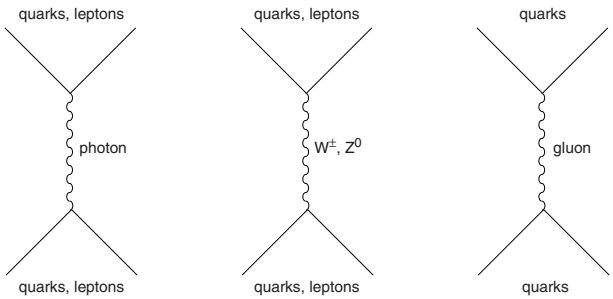

Figure 1. The fundamental forces between elementary particles are mediated by intermediate bosons: the photon of electromagnetism, the massive $W^{\pm}$ and Z^0 bosons of the weak interactions and the gluons of the strong interactions.

From the 1940s onwards, many strongly interacting particles (HADRONS) were discovered. It was proposed in 1964 that these could all be understood as composite bound states of more elementary entities called QUARKS. At that time, all the known hadrons could be constructed out of just three quark species of spin 1/2 and fractional charge Q: up ($Q = 2/3$), down and strange ($Q = -1/3$). Such pointlike constituents inside protons were discovered by experiments at SLAC in 1968. Initially it was a puzzle how quarks could appear almost free at high energies, corresponding to short distances, but were never seen singly, only confined inside hadrons. This puzzle was resolved when it was demonstrated that the couplings of gluons became weaker at high energies (short distances), a property known as asymptotic freedom.

Shortly afterwards, a key step in the establishment of the Standard Model was the discovery in a neutrino experiment at CERN in 1973 of a novel type of weak interaction, called neutral currents, in which the charges of the participating particles do not change, in contrast to the familiar weak interactions, called charged currents, in which the charges of participating quarks and leptons do change. Such neutral-current interactions were predicted by many unified theories of the weak and electromagnetic interactions, and their discovery provided the first circumstantial evidence that some such unified theory might be correct. The second piece of evidence for such a theory was provided by the discovery in accelerator experiments at BNL and SLAC in 1974 of hadrons containing a fourth quark constituent weighing about $1\frac{1}{2}$ GeV. This was baptized charm and had been predicted by unified electroweak theories, in order to explain the fact that neutral-current interactions that would change quark type, e.g. strange $\rightarrow$ down, are very suppressed, whereas there do exist charged-current interactions: strange $\rightarrow$ up. The charm discovery briefly pre-dated the τ lepton discovery mentioned earlier. Consistency of the simplest unified electroweak theory then required the existence of two more quark types, and the first of these (bottom), weighing about 5 GeV, was discovered in an accelerator

experiment at FNAL in 1977. The spectrum of quarks was apparently completed by the discovery at FNAL in 1995 of the top quark, which weighs about 175 GeV.

The mathematical framework for theories of particle interactions is provided by gauge theories, which offer the only consistent description of the interactions of spin-1 particles. A gauge theory is based on a continuous internal symmetry, e.g. changing the phase of the quantum-mechanical wave function in the case of the prototype gauge theory, QED. When one makes this symmetry local, i.e. allows space-dependent phase transformations, one must introduce a spin-1 gauge field. This is analogous to the way Einstein realized general coordinate invariance with a spin-2 metric field. Gauge theories differ in their choice of gauge group and in the group transformation properties of the matter particles. In the case of the Standard Model, the strong interactions are described by a theory transforming the wave functions of quarks, called QCD. The unified electroweak interactions are described by a combination of transformations acting on both quarks and leptons, first written down by Glashow in 1961, Weinberg in 1967 and Salam in 1968.

The establishment of the Glashow–Weinberg–Salam model as the correct unified electroweak theory proceeded in several steps over the following decade. A series of detailed experiments refined measurements of the neutral currents, verifying that their properties were consistent with the Glashow–Weinberg–Salam model. A crucial step was the observation at SLAC in 1978 of parity violation in deep-inelastic electron–proton scattering, which was followed by similar observations in atomic physics. The culminating step was the discovery of the weak intermediate bosons, $W^{\pm}$ for the charged-current weak interactions and Z^0 for the neutral currents, in proton–antiproton collisions at CERN in 1983.

Subsequent developments have been dominated by a series of precision tests of the Standard Model, including both its strong and its electroweak sectors. In a number of experiments at energy scales varying from about 1 GeV to about 200 GeV, it has been shown that the strong nuclear interactions indeed weaken at higher energies, as seen in figure 2. The 'strong' interactions are truly strong only at energy scales $\lesssim$1 GeV, corresponding to distances $\gtrsim$0.2 fm, where quarks are confined within hadrons. Detailed calculations of hadron spectroscopy require extensive numerical simulations of discretized (lattice) versions of QCD on powerful computers. These are currently able to reproduce experimental measurements to within a few per cent. Calculations at higher energies (shorter distances) may be made using techniques from quantum field theory. They predict an energy dependence of the strong coupling that is in very good agreement with the experimental measurements shown in figure 2. This concordance confirms that there are no other light strongly interacting elementary particles beyond the gluons and quarks introduced earlier. The present data shown in figure 2 indicate that the strong coupling strength, analogous to the fine-structure constant of QED, has

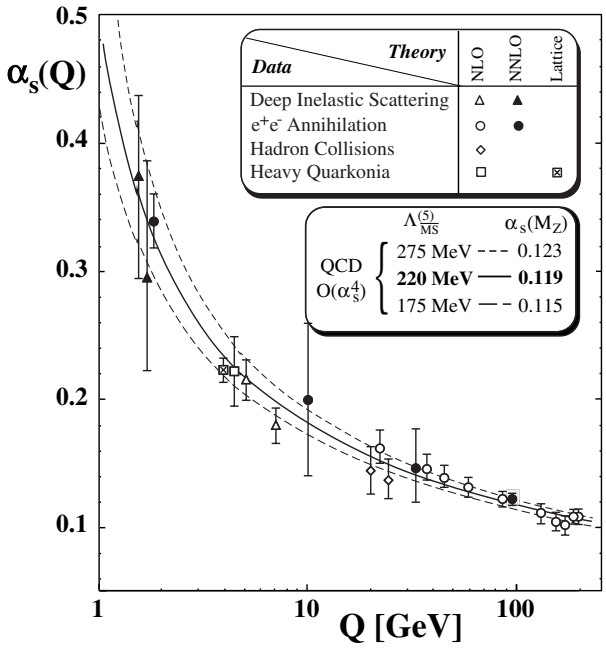

Figure 2. Weakening of strong interactions at high energies.

the value 0.119 ± 0.004 when measured at an energy corresponding to the mass of the Z^0 weak intermediate boson.

Tests of the electroweak sector of the Standard Model have been dominated by high-energy experiments on e^+e^- collisions at CERN, using the LEP accelerator, and at SLAC, using the SLC accelerator. A compilation of LEP measurements of the cross sections for e^+e^- annihilation into charged-lepton and quark–antiquark pairs is shown in figure 3. This is dominated by the Z^0 resonance peak, which must be one of the most carefully studied Breit–Wigner resonances in physics, with about 2×10^7 decays observed and measured. The height and width of the peak depend not only on the observed Z^0 decay modes but also on possible unseen decay modes such as those into neutrino–antineutrino pairs. Extra invisible decays would shorten the Z^0 lifetime and hence, by the UNCERTAINTY PRINCIPLE, increase the natural width of the Z^0 resonance peak. The measurements shown in figure 3 tell us that there are precisely three neutrino species, no more and no less. These correspond to the three known charged leptons, the electron, muon and tau. According to the Standard Model, there can only be three corresponding pairs of quarks. We therefore think there can be no further quarks beyond the six already known.

The data shown in figure 3 provide a very accurate determination of the mass of the Z^0: 91.1867 ± 0.0021 GeV. To arrive at this precision, it was necessary to take into account many effects that were considerably larger than the quoted error. These included terrestrial tides, which caused the LEP machine to expand and contract, and hence its energy to vary by $O(10)$ MeV, and even the passing

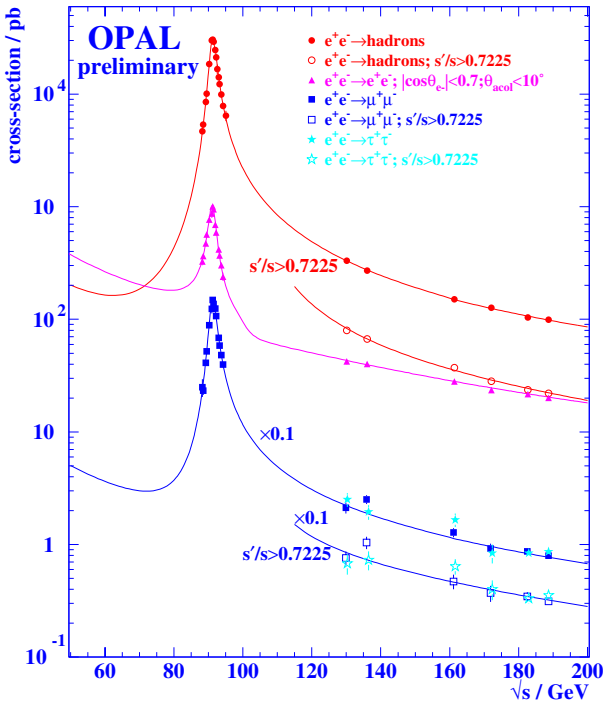

Figure 3. Cross sections for e^+e^- annihilation into charged-lepton and quark–antiquark pairs.

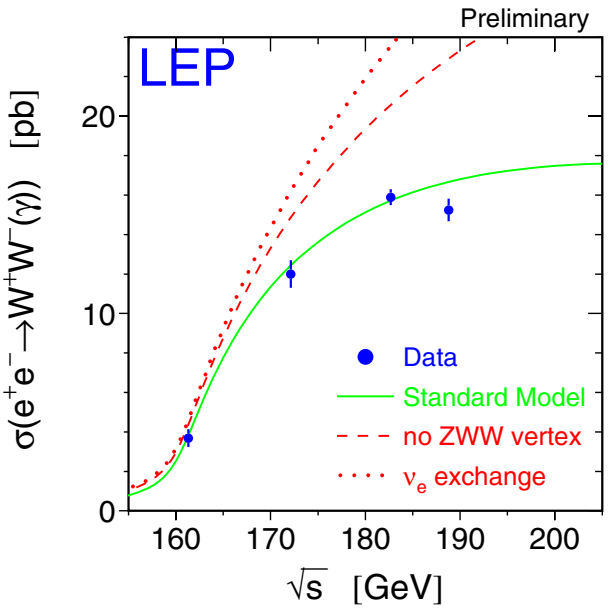

Figure 4. Production of W^+W^- boson pairs.

of nearby electric trains, which generated stray electric currents that perturbed the magnets of LEP and thus its beam energy.

In addition to the cross-section measurements shown in figure 3, LEP and the SLC have provided many other precision measurements, including branching ratios for Z^0 decays into different modes such as heavy quarks, forward–backward production asymmetries and polarization effects. Many of the measurements have per mille accuracy, and none differs significantly from the Standard Model prediction, and all measurements are within 1 or 2 standard deviations. These predictions require detailed calculations in quantum field theory, which were shown to be possible by 't Hooft in 1971. As was emphasized by Veltman, in particular, these calculations are sensitive to the masses of heavy particles that are too heavy to be produced directly at LEP or the SLC. The successes of these calculations were used successfully to predict the mass of the top quark, before it was discovered.

Referring back to figure 3, we see that LEP measurements extend to centre-of-mass energies considerably above the Z^0 peak. One of the principal Standard Model tests possible with higher-energy data is the production of pairs of $W^\pm$ bosons, as shown in figure 4. According to the Standard Model, this reaction receives contributions from the exchanges of the neutrino, photon and Z^0. The first of these is required by the role of the $W^\pm$ bosons in β decay, the second by the electric charge of the $W^\pm$ and the third by the characteristic $Z^0W^+W^-$ coupling of the unified electroweak theory. As seen in figure 4, all these three contributions are required to explain the LEP data, and the values of the couplings extracted from the data are in good agreement with the Standard Model. These data may also be used to measure the mass of the $W^\pm$, and the results are also in good agreement with the Standard Model predictions.

Thus far, we have seen that the Standard Model is passing its experimental tests with flying colors. However, there are still some key features of the Standard Model that have not yet been tested. One of these is the origin of the particle masses. According to the Standard Model, the underlying field theory is formulated in terms of massless particles, and one must find some way to incorporate their masses without spoiling the successes of the theory. This is possible if there exists an additional, as yet unseen, particle called the Higgs boson. The precision electroweak data described earlier are sensitive to the mass of this particle, and currently indicate that it weighs about 100 GeV, with an uncertainty of a factor of about 2. The search for the Higgs boson has been one of the continuing objectives of the LEP experimental program. At the time of writing, these searches have so far been unsuccessful and have established that its mass must exceed about 108 GeV. By the end of its operation, experiments at the LEP accelerator should tell us whether the Higgs boson weighs less than about 114 GeV. Beyond this mass, the full range of possible Higgs masses up to about 1 TeV can be explored at CERN's LHC accelerator, which is scheduled to start taking data in 2005.

Another missing element in tests of the Standard Model is its mechanism for matter–antimatter asymmetry.

The weak interactions were shown in 1957 to violate not only parity (mirror) symmetry, but also charge conjugation. At first, it was thought that the combination of parity and charge conjugation, called CP, might yet be a good symmetry. However, an experiment in 1964 discovered that CP was also violated in the weak decays of some neutral composite particles called kaons. This means that matter does not behave in exactly the same way as ANTIMATTER, even if one reflects the experiment in a mirror in an attempt to recover the symmetry. In 1973, Kobayashi and Maskawa realized that this matter–antimatter asymmetry could be accommodated within the Standard Model if there were at least six quark species, as we now know to be the case. Subsequently, much theoretical effort has been devoted to evaluating the Standard Model predictions for matter–antimatter asymmetries in different processes, and there is an extensive experimental program to test these predictions. Follow-up experiments on neutral kaon decays are consistent with the Standard Model, but have not yet reached the sensitivity required to verify the characteristic predictions of the Standard Model. A number of experiments are planned to explore its predictions for CP asymmetries in the decays of mesons containing bottom quarks. There is good reason to expect that these experiments will be able to explore these matter–antimatter asymmetries at the levels predicted by the Standard Model.

It may be appropriate at this stage to mention some ways in which astrophysics and cosmology are sensitive to aspects of the Standard Model (see also PARTICLE ASTROPHYSICS). The energy production of main-sequence stars is controlled by nuclear physics and weak β decay, but details of the Standard Model are not directly relevant. These are, however, relevant to objects that are denser and/or hotter, such as collapsing supernovae. Weak neutral-current processes are essential to the understanding of neutrino emission from the collapsing core, and perhaps to the ejection of outer layers of the supernova progenitor. The nuclear equation of state of the remnant may also be sensitive to the underlying QCD theory of the strong interactions. In particular, it is often conjectured that under certain circumstances there may be a transition from conventional nuclear matter to quark matter, possibly with a high fraction of strange quarks.

Looking back to early cosmology, weak neutral-current processes also played an essential role in the reheating and decoupling of neutrinos around the epoch of big bang NUCLEOSYNTHESIS. Prior to that, in standard big bang cosmology the temperature of the early universe, and hence the characteristic particle energies, is believed to have increased as the inverse square of the age of the universe. When it was less than about 10^{-5} or 10^{-6} s old, hadrons would have been 'ionized' into quarks and gluons, and the Standard Model must be used to describe the behavior of the universe at these early times. The laboratory successes of the Standard Model described earlier imply that we possess the basis for a quantitative description of physics in the early universe.

When it was less than about 10^{-10} or 10^{-12} s old, it is thought that the Standard Model underwent a phase transition, before which all the particles of matter would have appeared massless, as well as the weak intermediate vector bosons and the Higgs boson. In addition to the familiar weak interactions, it is thought that other effects in the Glashow–Weinberg–Salam model, that have not been seen in the universe today, would have been important at this early epoch. These effects would have the distinctive feature of violating both baryon and lepton number by 3 units. Hence they must be taken into account in any attempt to understand the baryon density in the universe.

Although the Standard Model of particle physics is very successful, with no confirmed accelerator data that contradict it, there are many theoretical reasons to consider it unsatisfactory and to expect some physics beyond the Standard Model. For example, even if one accepts the quantum numbers of the quarks and leptons as given, the Standard Model contains 19 free parameters that are taken from experiment. These include three independent interaction strengths and a CP-violating parameter for the strong interactions, six quark masses and four parameters to describe how they are mixed by the weak interactions, three charged-lepton masses, the $W^{\pm}$ and Higgs boson masses. Having so many parameters is surely unacceptable for any candidate for a theory of everything, and attempts to go beyond the Standard Model typically try to simplify one of its aspects.

In a GRAND UNIFIED THEORY one regards the strong, weak and electromagnetic interactions as different aspects of a single interaction with a universal coupling strength. This is made possible by the fact that coupling strengths vary with energy, as exemplified by the asymptotic freedom of the strong interactions shown in figure 2. Calculations indicate that the coupling strengths may become equal at an energy around 10^{15}–10^{16} GeV. Many grand unified theories predict additional perturbative interactions that violate baryon and/or lepton number. These exotic interactions may cause baryons to decay and/or give neutrino masses. There have been many unsuccessful searches for proton decay, and its lifetime must be at least 10^{32} yr. Evidence has recently emerged from studies of solar and atmospheric neutrinos that they may have masses. If confirmed, this would constitute the first concrete evidence for physics beyond the Standard Model.

Other proposals for possible physics beyond the Standard Model try to understand the complicated pattern of lepton masses and quark masses and the way they are mixed by the weak interactions. One of the ideas often discussed in this context is the possibility that leptons and quarks are not elementary but composite bound states of more fundamental constituents. So far, no compelling model of this type has emerged, so it will not be discussed further here.

A third set of proposed extensions of the Standard Model arises from attempts to understand better the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

observed magnitudes of particle masses. The principal issue here is that the physical values observed seem to require very delicate fine tuning of the parameters of the Standard Model, which strikes many physicists as unnatural. One way to avoid this is to postulate that the Standard Model particles are accompanied by partners with identical internal properties and interactions, but with spins differing by half a unit. These 'supersymmetric' particles would have opposite statistics from the familiar Standard Model particles—normal matter particles such as quarks and leptons are fermions, and would be accompanied by new bosonic particles, whereas intermediate bosons such as the photon would be accompanied by new fermions (see SUPERSYMMETRY). The fine-tuning problem of the Standard Model would be avoided if the supersymmetric partners of Standard Model particles weigh less than about 1 TeV.

These possible extensions of the Standard Model may provide the frameworks for resolving many of the fundamental issues in astrophysics and cosmology. One of these is DARK MATTER. The cold component may be provided by massive stable neutral particles, for which one candidate is the lightest supersymmetric particle, that is expected to weigh $O(100)$ GeV. This possibility will be explored by forthcoming accelerator searches at the proton–antiproton collider at FNAL and at the LHC proton–proton collider at CERN. A hot dark matter component may be provided by massive neutrinos. The indications for neutrino masses from the solar and atmospheric neutrino data do not, however, require any neutrino to be heavy enough to make a significant contribution to the overall dark matter density, although there could be some consequences observable by astronomers.

A second cosmological issue that may be addressed by extensions of the Standard Model is the origin of the matter in the universe. This can be calculated in terms of elementary-particle interactions if they violate baryon number, if they exhibit a matter–antimatter asymmetry and if they depart from thermal equilibrium. As has been discussed above, there are Standard Model interactions that violate baryon number and matter–antimatter asymmetry. Whether they departed from thermal equilibrium in the early universe depends in the Standard Model on the mass of the Higgs boson. The LEP lower limit on its mass, combined with theoretical calculations, indicates that there would have been no significant departure from thermal equilibrium if the Standard Model was sufficient to characterize early cosmology. Therefore some extension of the Standard Model appears necessary to explain the baryonic matter in the universe (see also BARYOGENESIS), which may be possible with grand unification and/or supersymmetry.

Grand unified theories may also be needed to explain the size, age and flatness of the universe via cosmological INFLATION. The measurements of perturbations in the COSMIC MICROWAVE BACKGROUND radiation suggest that they originate from physics at an energy scale of 10^{13}–10^{16} GeV. This is far beyond the scale of particle masses in the Standard Model and comparable with the scale of grand unification estimated using data from LEP and other accelerators.

Finally, we note that many theorists believe that the underlying theory of everything that resolves all the open problems of the Standard Model should be provided by some incarnation of STRING THEORY. This is an apparently consistent quantum theory of gravity, requires supersymmetry and is rich enough to accommodate a grand unified theory. If the self-coupling of the string is strong, it may provide a correct numerical estimate of the scale of grand unification. Astrophysics and cosmology, via inflation, gravitational waves and perhaps a cosmological constant may provide the most important tests of this ultimate extension of the Standard Model.

Star Clusters

Even a small telescope shows obvious local concentrations of stars scattered around the sky. These star clusters are not chance juxtapositions of unrelated stars. They are, instead, physically associated groups of stars, moving together through the Galaxy. The stars in a cluster are held together either permanently or temporarily by their mutual gravitational attraction.

The classic, and best known, example of a star cluster is the Pleiades, visible in the evening sky in early winter (from the northern hemisphere) as a group of 7–10 stars (depending on one's eyesight). More than 600 Pleiades members have been identified telescopically.

Clusters are generally distinguished as being either GALACTIC OPEN CLUSTERS or GLOBULAR CLUSTERS, corresponding to their appearance as seen through a moderate-aperture telescope. Even in a relatively small telescope, the stars in an open cluster can be individually distinguished right at the center, whereas a globular cluster typically appears to consist of a sprinkling of bright, resolved stars superposed on a continuous background of unresolved fainter stars. Although the original distinction of the two classes of clusters was based almost entirely on their visual appearance, we now know that the globulars and the open clusters are very distinct from one another in almost every respect.

At the opposite extreme of concentration from the globular clusters are the stellar associations, loose, unbound groups of stars with particular spectral properties. Associations are normally observed as widespread regions with an excess density of spectral type O and B stars ('OB ASSOCIATIONS') or T TAURI STARS ('T associations'). In principle, there could be other types of association as well. It is not uncommon to find one or more open clusters at the core of a stellar association. The implication is that the stars in the central cluster or clusters and the surrounding association all formed more or less at the same time out of the same material. Since the association is not a gravitationally bound system, after a relatively short period of time, its stars will disperse and the association will lose its identity; for that reason, associations always consist of young stars.

The stars in an unbound association or a cluster that is evaporating will nevertheless all be moving with almost identical velocities, so at some later time, one might expect to find stars spread out in space, but still moving with similar velocities. Stars selected by velocity are sometimes called MOVING GROUPS. The best known of the moving groups is called the Hyades moving group. It consists of a number of stars, located in all directions from the Sun, which share the space motion of the Hyades star cluster. However, it is uncertain whether these stars share a common origin with the Hyades cluster.

The category of moving groups is not to be confused with moving clusters. These are clusters near enough to the Sun that all three dimensions of their motion through the Galaxy can be used to derive the cluster distance, independently of parallax measurements.

A final category of clusters has recently been identified based on observations with infrared detectors. These are the embedded clusters—star clusters still in the process of formation, and still embedded in the clouds out of which they formed. Because it is possible to see through the dust much better at infrared wavelengths than in the optical, these clusters have suddenly become observable.

Star clusters are of considerable astrophysical importance to probe models of stellar evolution and dynamics, explore the star formation process, calibrate the extragalactic distance scale and most importantly to measure the age and evolution of the Galaxy.

Definition of a star cluster—cluster catalogs

Just what *is* a cluster? How many stars does it take to make a cluster? Trumpler in 1930 defined open clusters as 'Star groupings which undoubtedly form physical systems (stars situated at the same distance and probably of the same origin) and which at the same time are sufficiently rich in stars for statistical investigation.' Since virtually all clusters have been discovered either by visual examination of the sky with a telescope, or from inspection of photographic or electronic images in the visual or infrared, an operational definition of a star cluster is suggested:

> A star cluster is defined to be an obvious concentration of several stars or more above the surrounding stellar background, apparently localized in space and identifiable on visual or infrared images covering a suitable field of view.

While this definition may seem imprecise, it conveniently includes most of those objects (in our Galaxy at least) listed in the existing cluster catalogs. At the same time, it excludes galaxy-sized systems or objects with insignificant numbers of stars. Presumably most clusters defined in this way are physical systems, although they may or may not be gravitationally bound systems. So some of the embedded clusters or slightly older, optically revealed clusters may be unbound star-forming regions in the process of dispersing. The above definition avoids the difficulty of distinguishing bound systems from unbound ones—if it looks like a cluster, it is a cluster.

From the theoretical point of view, a cluster might be better defined as a self-gravitating system of stars residing within the Galactic gravitational potential. Using this definition, unbound embedded clusters or young optically revealed clusters would not be considered to be true clusters. In addition, a star that has achieved escape velocity from a cluster but is still within the tidal radius of the cluster would be considered to be a nonmember by this theoretical definition, but would be a member by the observational definition.

Few objects have been catalogued as extensively as star clusters. The MESSIER CATALOG of 107 nonstellar objects includes 59 objects now known to be star clusters. The

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

first major catalog that includes clusters is the NEW GENERAL CATALOG (NGC), listing 487 clusters. The update to the NGC, the IC, contains another 30 clusters.

There have been at least a couple of dozen other more or less systematic attempts to search for and catalog additional star clusters. The entire sky has now been searched for clusters to the limiting magnitude and resolution of the wide-field Schmidt telescope photographic surveys. Unfortunately, the large number of partly redundent catalogs has generated a considerable amount of confusion about cluster names, and some clusters have almost a dozen aliases. The existing cluster catalogs are almost certainly biased in various ways, and any statistical results based on them are subject to systematic errors and selection effects of one sort or another.

As the number of catalogs has grown, and as the astrophysical importance of star clusters has been more appreciated, the number of secondary catalogs, summarizing the known properties of clusters, has also grown. Some useful catalogs are given in the Bibliography.

Summary of cluster properties

Table 1 summarizes the properties of star clusters. While there is a considerable dispersion in the properties of individual clusters, as well as a substantial uncertainty in some of the values, these numbers are representative of the cluster systems.

Table 1 shows that there is a rather sharp distinction between the globular clusters, which are representative of the Population II stars of the galaxy, and the open clusters (including the OB associations, moving groups and embedded clusters), which are Population I stars. The most massive of the open clusters are roughly the same as the least massive globulars, and the oldest of the open clusters is no older than the youngest of the globulars.

Globular clusters

The known globular clusters in our Galaxy number about 147 and, taking into account obscured regions of the Galaxy, the total Galactic population of globulars is probably about 200. Most of the 'missing' globulars are likely to be located close to the Galactic center or near the Galactic plane on the far side of the Galaxy.

The globulars are substantial stellar systems. Even the smallest of them contain some 10 000 solar masses of stars and a few, such as M22 and Omega Centauri, exceed one million solar masses.

As described later in this article (see also STELLAR DYNAMICS), the stellar distribution within a globular cluster is well represented by King models, which can be characterized by two parameters: the central surface brightness and the core radius, defined to be the radius at which the brightness drops to one-half the central value. Once these two parameters are determined, the appropriate King model will yield a tidal radius for the cluster. The globular clusters cover a substantial range in size. The median core radius is close to one parsec, but a few clusters in the outer halo of the Galaxy have core radii in excess of 10 parsecs. The median tidal radius is about 35 parsecs, but again there are some in the outer halo with much larger tidal radii.

Open clusters

Some 1200 open clusters have been catalogued, but as many as 250 of these appear to be simply slight enhancements in the stellar density along a line of sight or small asterisms of unrelated stars. Such asterisms should not be considered as clusters by either of the definitions of clusters given above. Most of the open clusters in the Galaxy have probably not yet been found, since open clusters are found near the Galactic plane where the interstellar dust is the most opaque. There may be as many as 10^5 open clusters in the Galaxy.

The smallest of the open clusters contain fewer than a dozen stars, so the minimum mass for an open cluster is about $10\,M_\odot$. At the other extreme, some of the most massive open clusters are old ones such as NGC 6791, with more than 10 000 members, again with typical masses near one solar mass. The most populous younger clusters contain a few thousand stars, but since their most massive stars are substantially more massive than the Sun, the total mass of some of the younger clusters exceeds $10^4\,M_\odot$.

Few if any open clusters have enough members to be characterized in terms of dynamically meaningful quantities, such as the core radius or tidal radius. Instead, open cluster sizes are based on the 'angular diameter' measurement where the diameter is the apparent size of the cluster as measured on the appropriate sky survey photographs. Even when the distance to the cluster is well-known, the angular diameter does not yield a well-defined linear dimension to the cluster. Nevertheless, there is a rather small spread in measured cluster diameters, the typical open cluster being between 4 and 5 pc in diameter. A few clusters are more than twice this size, and some are only one or two parsecs in diameter, but the majority fall rather close to this value. The core radius of open clusters is probably roughly 1 pc, that is to say, about the same as the typical core radii of globular clusters. There is no strong correlation of cluster size with age, although several of the oldest clusters are somewhat larger and some of the very youngest clusters are also larger. Nor is there any correlation of cluster size with Galactic location or with the number of members.

OB associations

OB associations are areas on the sky with a higher than normal density of O and B stars, They are both large and diffuse; they are in fact sufficiently amorphous that distinct boundaries are hard to define. They typically cover many tens of parsecs and often contain one or more discrete clusters within their borders. Their diffuse nature makes it impossible to identify fainter stars as being members of associations, although there may well be large numbers of lower-mass stars that formed from the same molecular cloud.

Table 1. Summary properties of star clusters.

	Globular clusters	Open clusters	OB associations	Moving groups	Embedded clusters
Numbers of clusters:					
Catalogued	147	1200	70	< 10	~ 25
Likely Galactic total	200	10^5	> 1000	—	—
Typical Sizes (pc):					
Core radius (median)	1.0	—	unbound	unbound	—
Tidal radius (median)	35	—	unbound	unbound	—
Apparent diameter	—	4	> 100	—	1
Masses ($M_\odot$):					
Minimum	10^4	10	1000	—	100
Maximum	10^6	10^4	10^4	—	> 1000
Ages (yr):					
Minimum	8×10^9	5×10^6	5×10^6	—	$< 10^6$
Maximum	16×10^9	9×10^9	2×10^7	—	5×10^6
Metallicities ([Fe/H]):					
Range	−2.3 to +0.2	−0.7 to 0.3	Pop I	Pop I	Pop I

Approximately 70 OB associations have been catalogued. An association may consist of as few as a dozen luminous O and B stars, but because they range in mass from about 10 $M_\odot$ to some 70 $M_\odot$, the total mass of the association may range from about 1000 $M_\odot$ to more than ten times that number.

Moving groups

Several moving groups have been identified, but because the group may be spread out over a large region of the galaxy, the membership of a group is likely to be seriously incomplete, assuming that the group has a common origin at all. No reliable estimates of the total mass of a moving group exist.

Embedded clusters

At the other extreme of size from associations are the embedded clusters. This newly identified class of object consists of groups of stars still deeply embedded in the nebulosity out of which they have just formed. They range from a few tenths of a parsec to about two parsces in diameter. They are found only through IR imaging surveys—it is important to stress that these surveys are now sufficiently extensive that the apparent small size of the embedded clusters is not just a result of inadequate sampling. They really are rather compact objects. Although a few, like the Orion Trapezium region, are rich systems with hundreds of stars, most of them consist of small aggregates of stars.

No comprehensive catalog exists, but as many as 25 embedded clusters have been described; the total Galactic population of embedded clusters probably exceeds this number by several orders of magnitude. Since the stars in an embedded cluster have not yet reached the main sequence, even the relatively low-mass stars are rather luminous. Consequently they are relatively easily observable (in the infrared). They are compact, very dense regions, containing hundreds to thousands of solar masses of stars.

If the embedded clusters are all smaller than the ordinary, optically visible open clusters, does the one class evolve into the other? That is to say, when the molecular clouds surrounding these embedded clusters dissipate in a few million years, will there be an apparent ordinary open cluster there, or will the stars dissipate as fast as the gas? The answer to this question is not yet known and is the subject of much discussion at the present time. Embedded clusters are sometimes called 'stellar aggregates' rather than clusters because of this ambiguity, but based on the definition of a cluster given here they should be considered as star clusters.

Cluster distances and the cosmic distance scale

Star clusters provide a critical step in the determination of the cosmic distance scale. The starting point for cluster distances, and a primary step in the distance scale, is the Hyades star cluster. As a result of the HIPPARCOS project, the distances to the individual stars in the cluster have been measured well enough that the three-dimensional structure of the cluster can be determined. The Hipparcos data plus additional support from other measurements show that the Hyades distance modulus is $(m - M)_o = 3.33 \pm 0.01$, that is, the center of the Hyades cluster is 46.3 ± 0.2 pc from the Sun.

To find the distances to more remote clusters, a standard technique is to relate the properties of the Hyades to those of the cluster in question. The primary mechanism for that comparison is the color-magnitude diagram, a form of HERTZSPRUNG–RUSSELL DIAGRAM. The Hertzsprung–Russell diagram shows the relation between the luminosities of stars and their temperatures; in a color–magnitude diagram the luminosity is presented as either the absolute or apparent magnitude and the temperature is represented by a color index. The color–magnitude

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

diagrams of two clusters will in general have the same shape, but will be shifted in magnitude by an amount equal to the difference in distance modulus between the two. There may also be additional shifts in magnitude and color index resulting from interstellar absorption. The general procedure is to apply the effects of absorption, if known, and then slide the diagrams of the two clusters until they match, according to some goodness-of-fit criterion.

The principal limitations of this method are the accuracy of the magnitudes and colors of the stars in both the Hyades and the target cluster, the amount of interstellar absorption to the target cluster (the interstellar absorption to the Hyades is effectively zero) and the effects of chemical composition on the location of the main sequence. The Hyades is rather unusually metal-rich (approximately [Fe/H] = +0.15) compared with most star clusters, which must be taken into account.

Figure 1 shows the color–magnitude diagrams of several star clusters, corrected for distance. M92 is an old, metal-poor globular cluster; 47 Tucanae is another old globular cluster, but less metal-poor; M67 is an old open cluster of solar composition, and the Hyades is a younger metal-rich open cluster. For comparison, the zero-age main sequence (ZAMS) for solar composition stars is shown as well. This diagram presents the combined effects of stellar evolution and chemical composition. The M92 main sequence lies the lowest in the diagram, as would be expected from its composition, 47 Tuc is next, then M67 and finally there are the individual Hyades stars, the most metal-rich ones in the diagram. The ZAMS line corresponds approximately to solar-compositon stars.

Figure 1 also shows that it is critical to have the right distance to a cluster. Except for the horizontal branches, the shapes of the color–magnitude diagrams for the two globular clusters are virtually identical. Unless both the distance and composition of a cluster are known very well, the age uncertainties that result are large.

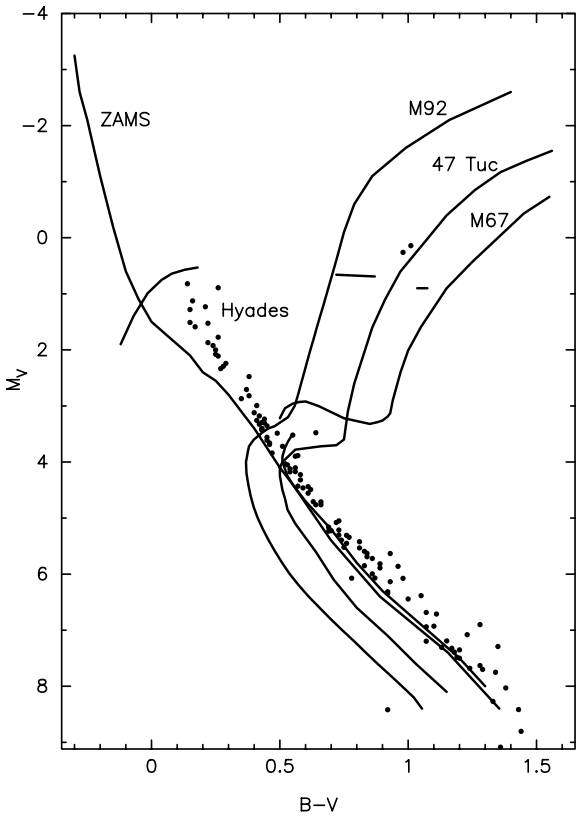

Figure 1. A composite of color–magnitude diagrams of the globular clusters M92 (from Stetson and Harris 1988) and 47 Tucanae (Hesser *et al* 1987) and the open clusters M67 (Montgomery *et al* 1993) and the Hyades (Perryman *et al* 1998). The zero-age main sequence (ZAMS) of Schmidt-Kaler (1982) is shown for comparison.

Clusters and stellar evolution—cluster ages

Star clusters represent snapshots of the process of stellar evolution—they are frozen in time from a human perspective. Since all the stars in a star-forming region begin their protostellar phase within a few million years of one another, the stars in a cluster much older than a few tens of millions of years can be considered to be all the same age. Thus the color–magnitude diagram of a star cluster represents the properties of stars differing in mass, but all of the same age and chemical composition. A critical test of the validity of STELLAR EVOLUTION models is to be able to predict the observed properties of cluster stars, as seen in the color–magnitude diagram.

To compare the models with the actual stars in a cluster, a series of model evolutionary sequences is computed for stars selected to have a range of masses. An isochrone is derived by interpolating in this series of models to find the parameters for stars all the same age. The isochrone is in effect a theoretical color–magnitude diagram.

In going from the theoretical predictions of the model isochrone to the observed color–magnitude diagram, there are a number of serious complications. In addition to the various physical and numerical uncertainties of the models themselves, a major complication relates to the transformation of the theoretical parameters, effective temperature and luminosity, into the derived absolute magnitude and color index. To make this transformation, a good knowledge of the stellar flux distribution is needed (a good model atmosphere), plus a knowledge of the details of the spectral response of a typical photometric system. The latter includes atmospheric transmission, telescope plus filter spectral response and the spectral sensitivity of the detector, all of these integrated over the flux distribution of the model star.

The problem of measuring the ages of star clusters appears to be a simple one. As figure 1 shows, the main sequence turn-off of a star cluster—usually defined as bluest point (i.e., the smallest value of the color index) along the cluster sequence—is a function of the age of the cluster. This follows naturally from the basic fact of stellar evolution that the massive, more luminous,

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

stars evolve away from the main sequence before the less massive stars have significantly changed. But at a given mass the actual age when this occurs depends on the chemical composition of the star, and possibly other factors as well, such as rotation. There are a number of theoretical uncertainties in addition to the observational uncertainties. Furthermore, as can be seen in figure 1, the shapes of the main-sequence/turn-off/red-giant region of old cluster color–magnitude diagrams are all roughly the same. So errors in the distance, interstellar reddening or composition can lead to a cluster being matched to a stellar model of the wrong age.

The most important of these difficulties is the distance. For example, if a cluster is measured to be too close by, say, 10%, then the measured luminosities of its stars will be too small by 21%. But the luminosity of a star is just a measure of the rate at which it is burning its nuclear fuel. So in this case, the distance error would mean that the nuclear-burning rate will be underestimated, and the cluster age would be overestimated by that same 21%. Very few clusters have their distances known to 10%, so while there are additional constraints that can be put on the age calculation, the uncertainties are still substantial.

The distance problem enters in two ways. First, the distances to individual clusters have random errors relating to the particular data for that cluster, but of more significance to astrophysics is the problem of the distance scale itself. The Hipparcos satellite has helped the situation considerably, but there is still considerable controversy over the ages of globular clusters.

Galactic distributions of clusters

Globular clusters

The globular clusters, containing the oldest stars in the Galaxy, are located in a nearly spherical distribution about the Galactic center. They make up the most visible component of the Galactic halo, and as a practical matter they define the stellar halo. Because they can be identified so readily and their distances measured reliably, Harlow Shapley was able to determine the direction and distance to the Galactic center in the 1920s. The globular clusters were later shown to define the Population II stars of the Galaxy.

Close examination of the statistics of the globular cluster properties shows that they can be divided into three subpopulations on the basis of cluster composition and the shape of the horizontal branch (see HORIZONTAL-BRANCH STARS). The 'old halo' clusters have horizontal branches consistent with a great age; the 'young halo' clusters have horizontal branches sugessting a somewhat younger age; and the 'disk globulars' are rather more metal-rich (with [Fe/H] > -0.8) than the other populations and are distributed in a thick disk shape.

The three subpopulations of clusters may have originated in two or three distinct processes. The old halo clusters probably formed in the initial collapse of the Galaxy and so their stars are the oldest. The disk globular clusters appear to be members of the thick disk population and may be significantly younger in addition to being more metal-rich. The young halo clusters may actually have been formed outside our Galaxy in nearby dwarf spheriodal galaxies that subsequently merged with our own Galaxy. The young halo clusters show no evidence for a correlation between Galactic position and composition, consistent with their having been injected into the Galaxy in random events. The old halo and disk subsystems do show correlations between galactocentric radius and composition, and there is a possibility that the old halo and thick disk populations may form a single system. If indeed this is true, then there is a regular, systematic trend between composition and position in the old halo plus thick disk subsystems, as well as between composition and age.

Open clusters

The open clusters, including associations, moving groups and embedded clusters, belong to the disk population of the Galaxy (the Population I stars). The vast majority of them are located close to the Galactic plane. Consequently, most known open clusters are within a couple of kpc of the Sun.

Assuming a distribution perpendicular to the Galactic plane of the form

$$N \propto \mathrm{e}^{z/z_0}$$

the scale length, z_0, for clusters with ages < 700 million years is about 55 pc, whereas the older clusters have a scale height of 350 pc. There is otherwise no correlation between composition and age or distance from the Galactic plane. There is, however, a distinct correlation between [Fe/H] and galactocentric radius, with the most metal-poor stars located in the far outer reaches of the Galactic disk.

The open clusters show no systematic trend of metallicity with age. At each age, there is a substantial range in composition, but on the average the oldest ones are approximately the same composition as the youngest ones.

Cluster dynamics

Star clusters are ideal laboratories for studies of stellar dynamics—they are simple systems consisting of what are essentially point masses, moving freely under the action of a single force, gravity. Consequently it is possible to model in some detail the dynamical evolution of star clusters. It is important to note, however, that the formalism of classical celestial mechanics is not directly applicable to star clusters. In celestial mcahanics, one usually considers the motion of one body in the potential field of another body (the two-body problem) or perhaps two other bodies (the three-body problem). However, a cluster consists of several (i.e., more than three) more or less equal masses moving in their mutual potential field, perhaps also perturbed by external (Galactic) forces.

Most dynamical models begin with the assumption that they are collisionless systems—that is, the forces acting on individual particles (stars) are long-range forces only, resulting from the gravitational potential field of the

aggregate of all the stars in the system. The occasional close encounters between pairs of stars, if they are included at all, are dealt with separately. More distant encounters may, however, be common in a stellar system. These encounters will gradually change the motion of an individual star, so that after enough such encounters, the star will have changed in velocity by an amount equal to the velocity. The time it takes for such a complete exchange of energy to take place is the relaxation time.

King models

Star clusters are approximately equivalent to isothermal spheres, that is to say, the velocities of stars in the cluster have a distribution that is independent, or nearly so, of the position of the star in the cluster. However, a singular isothermal sphere has infinite density at the origin (i.e, the center) and therefore infinite mass. To represent an isothermal sphere in a well-behaved manner at the origin, it is possible to define dimensionless variables, where the radius variable

$$\tilde{r} \equiv \frac{r}{r_0}$$

is defined by the King radius,

$$r_0 \equiv \sqrt{\frac{9\sigma^2}{4\pi G\rho_0}}.$$

At the radius r_0, the density within the system has fallen to 0.5013 of its central density. Since the core radius, r_c, as defined observationally is the radius at which the density has fallen to just half the central density, r_0 is often called the core radius.

For a system with gravitational potential Φ, where a single particle has velocity v and total energy E, the relative potential Ψ and relative energy $\mathcal{E}$ of the particle can be defined as

$$\Psi \equiv -\Phi + \Phi_0 \quad \text{and} \quad \mathcal{E} \equiv -E + \Phi_0 = \Phi - \tfrac{1}{2}v^2$$

where Φ_0 is some constant. A modified form of an isothermal sphere is the King model, which resembles the isothermal sphere at small radii, where most of the particles (stars) have large values of $\mathcal{E}$, but gradually becomes less dense than the isothermal sphere at larger radii where $\mathcal{E}$ tends to be lower. By suitably defining the constant Φ_0 so that at some critical relative energy $\mathcal{E}_0 = 0$, the phase-space distribution function of the King model can be defined so that for $\mathcal{E} \gg 0$ the King model and the isothermal sphere are identical, and for $\mathcal{E} \leq 0$ the King model distribution function is zero.

This leads to a family of models for the density distribution within the system that are defined by the central relative potential, $\Psi(0)$, where the radius is in units of the King radius, r_0. At the radius where Ψ falls to zero, the density also falls to zero. This is the tidal radius, r_t. The log of the ratio of the tidal radius to the King radius defines the concentration of the cluster,

$$c \equiv \log_{10}(r_t/r_0).$$

King models with c between 0.75 and 1.75 fit globular clusters well.

Observationally, the central surface brightness, Σ_K, and the core radius, r_c, can be used in place of $\Psi(0)$ and r_0.

Bibliography

Much of the information from older cluster catalogs and other sources is now online in the SIMBAD database.

A rather complete catalog of information on the known globular clusters is maintained by W E Harris on the website:

http://physun.physics.mcmaster.ca/Globular.html

This catalog is also discussed in

Harris W E 1996 A catalogue of parameters for globular clusters in the Milky Way *Astron. J.* **112** 1487

The ages of the globular clusters are discussed in

Chaboyer B, Demarque P, Kernan P J, Krauss L M 1998 The age of globular clusters in light of Hipparcos: resolving the age problem? *Astrophys. J.* **494** 96

The dynamics of the globular clusters are described in detail in

Binney J and Tremaine S 1987 *Galactic Dynamics* (Princeton: Princeton University Press)

Open cluster data can be found in the SIMBAD database, which includes the *Catalogue of Open Cluster Data, Fifth Edition* (1987) compiled by G Lynga (Lund Observatory).

A database of photometric and spectroscopic information on open clusters called WEBDA is maintained at the Geneva Observatory at:

Star Diagonal

A device that fits in the draw-tube of a telescope to enable an object to be viewed at right angles to the direction in which the telescope is pointing. In such a device, light is reflected through a right-angle either by a flat mirror inclined at an angle of 45° to the optical axis or by means of total internal reflection in a prism. The resulting image is reversed left-to-right.

It is often convenient to use a star diagonal when observing objects close to the zenith so as to avoid placing the observer's head at an awkward angle.

A related device, the solar diagonal, uses an unsilvered mirror, or a thin prism called a Herschel wedge, so as to reflect only a small proportion of the incoming solar radiation (typically about 5%), thereby reducing the amount of light and heat that reaches the eyepiece.

See also: telescope, zenith.

Star Formation

The formation of stars is an ongoing process that continues to the present day. Star formation is most easily observed in the Milky Way, and these observations, the focus of this article, have led to a working model for the formation of low mass stars like our Sun. In this picture, stars form from the gravitational collapse of the cold, molecular interstellar material (gas and dust) that resides in structures known as INTERSTELLAR MOLECULAR CLOUDS. In the dynamical collapse and ACCRETION of infalling matter, a circumstellar disk forms around the accreting star as a consequence of the finite ANGULAR MOMENTUM of the molecular cloud. Stars obtain a significant fraction of their mass by accretion through their disks, and disk matter is a reservoir for the formation of stellar and planetary mass companions (see ACCRETION DISKS). Additional processes such as winds and magnetic accretion flows are believed to be responsible for the removal of angular momentum that allows the star to continue to grow in mass. These processes are combined in our current view of how Sun-like stars obtain their initial masses and angular momenta, i.e., the initial conditions for subsequent STELLAR EVOLUTION. The extent to which this picture, developed to explain the formation of low mass stars, applies to the formation of more massive stars, is an active area of research.

Observed properties of young stars

Infall

As is well known, molecular clouds are the reservoirs of mass and angular momentum from which stars form. However, while it has been appreciated for some time that star formation probably involves a phase of dynamical collapse (rather than quasi-static contraction, for example), the actual detection of infalling motion associated with the star formation process has only been made convincingly in the last few years. Since the mid-1970s, the many molecular line studies of molecular cores, the centrally concentrated regions within molecular clouds from which stars form, have typically revealed evidence for gas engaged in outflowing rather than infalling motion. The now apparent ubiquity of stellar outflows has remained one of the primary obstacles to the detection of infall owing to their often significant impact on the dynamics of the gas surrounding the star.

As a result, the successful detection of infalling motion has hinged on the choice of appropriate targets and suitable line diagnostics. The very young, so-called 'class 0', sources have turned out to be particularly fruitful sources for study. This is in part because the outflows in these sources are less well developed than in older sources and are often directed in the plane of the sky, thereby minimizing their contribution to line profiles.

The signature of dynamical infall seen in these sources is a double-peaked line profile with the blue peak stronger than the red (e.g. Zhou *et al* 1993; see also figure 1). This characteristic profile arises from the centrally peaked density and temperature distributions of the infalling gas, which produce an outwardly decreasing excitation gradient. In the simple but illustrative case of spherical infall, the central absorption is produced by low-velocity, low-excitation foreground gas in the core which is seen in absorption against the emission from more centrally located, higher-excitation gas. Because in general low-excitation, redshifted gas is seen in absorption against higher-excitation, redshifted gas further along the line of sight, while the situation is reversed for the blueshifted gas (higher-excitation gas lies in front of lower-excitation gas), the red side of the profile is preferentially weakened relative to the blue side (see, e.g., figure 8 in Zhou *et al* 1993). A key factor in the detection of this dynamical signature is the choice of appropriate line diagnostics. These must be sufficiently excited in regions where the excitation gradient is large and have optical depths sufficient to manifest the effect.

As described by Zhou *et al* (1993) in their multiline transitional study of the class 0 source B335, the theoretical solution of spherically symmetric dynamical collapse (Shu 1977), when coupled with a radiative transfer analysis, provides an excellent fit to the suite of observed CS and H_2CO line profiles (see also Choi *et al* 1995; figure 1). Because physical situations other than infall can also produce a double-peaked profile (e.g. broad emission plus an unrelated foreground absorber; alternatively, outflow), multitransitional studies are important in confirming infall and in ruling out other possibilities. For example, in regions undergoing infall, higher-excitation lines are predicted to be broader than lower-excitation lines, an effect which would not be observed in the absence of systematic motions. Additionally, stronger blueward line asymmetries are predicted for more optically thick lines in the case of infall, an effect which is observed.

Since the infall velocity gradient is measurable, albeit only on small size scales ($\sim 20''$ for the nearest sources), spatial maps of line emission from molecular envelopes have been obtained in order to confirm that the gas is undergoing dynamical infall. Such studies find larger linewidths and line asymmetries closer to the forming star (e.g. Myers *et al* 1995) and can even be used to diagnose the presence of rotational motion in the infalling gas (Zhou *et al* 1996). Line profiles observed in the latter case are in good agreement with theoretical models of dynamical collapse that include the effects of rotation (Terebey *et al* 1984).

From the modeling of multiple line profiles, it is possible to extract physical and dynamical information about the infalling gas, such as the mass accretion rate, the mass of the star + disk and the time period over which collapse has been occuring (e.g. Zhou *et al* 1993; Choi *et al* 1995; Zhou *et al* 1996). In a recent development, infalling motions have been detected in a molecular cloud core that is not known to have a star embedded within it (Tafalla *et al* 1998). This development opens up the possibility of studying the very early stages of the star formation process using the above techniques. The detail with which the infall process can now be studied and the close agreement between observations and theoretical

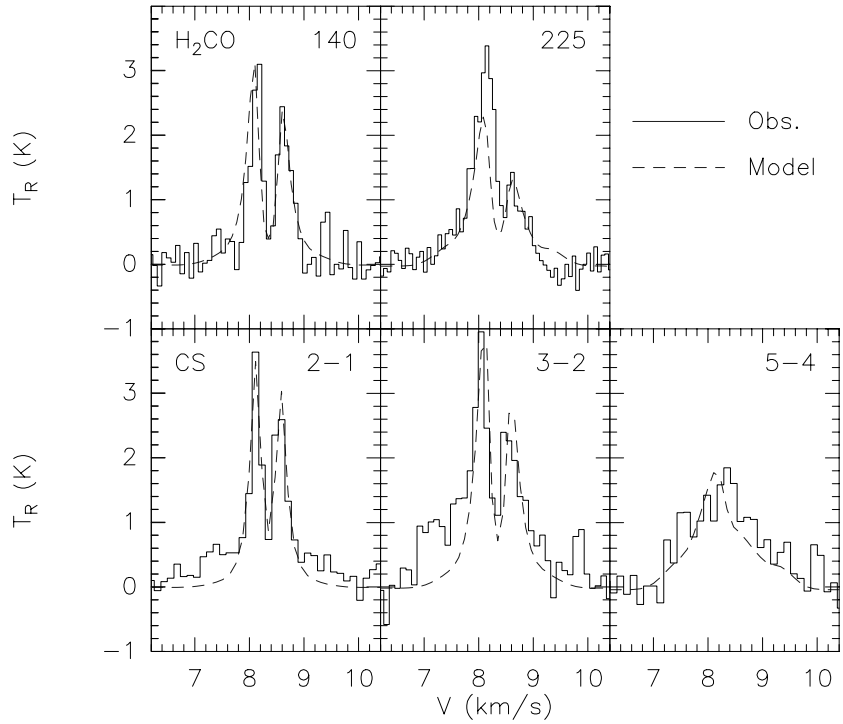

Figure 1. Rotational transitions of H_2CO (140 and 225 GHz) and CS ($J = 2$–1, 3–2 and 5–4) observed toward the very young class 0 source B335 (histogram) and the best-fit model spectra (dashed curve) under the assumption of dynamical 'inside-out' collapse (Choi *et al* 1995). The close agreement between the data and the theoretical model provides strong evidence for a phase of dynamical collapse in the process of star formation.

predictions together appear to provide the long-sought observational evidence that stars build up their masses and angular momenta through molecular cloud collapse and a dynamical accretion process.

Outflow

As described above, outflows are a ubiquitous and unexpected signature of star formation. At the very early stages of stellar evolution, when the star is still embedded in the molecular cloud from which it formed, the outflow process manifests itself in several ways. On the largest size scales (parsecs) are molecular outflows which are typically detected in molecular emission lines at millimeter wavelengths (e.g. Lada 1985; Bachiller 1996). The outflows commonly display a bipolar morphology with physically separated lobes of cold red- and blue shifted gas (e.g. L1551—Snell and Schloerb 1985). The low velocities ($\sim$10 km s^{-1}) and large masses ($\gtrsim 1 M_\odot$) of the outflows indicate that they are swept-up molecular cloud material. This interpretation is sometimes supported by molecular line observations which show that the outflowing gas is distributed in a shell-like structure that surrounds a lower-density cavity (e.g. L1551—Moriarty-Schieven *et al* 1987). Since the large momenta of the outflows suggest that they may reverse the motion of the infalling gas and thereby limit the mass of the star, the origin of outflows is of considerable interest.

Support for the idea that molecular outflows are swept up by an energetic wind originating close to the star comes from the morphology of REFLECTION NEBULAE within $\sim$1000 AU of the star which also imply a cleared polar region (e.g. L1551—Davis *et al* 1995). Often collinear with the lobes of molecular outflows are highly collimated emission line jets (e.g. L1551—Davis *et al* 1995) which are detected at optical and now IR wavelengths (see e.g. Edwards *et al* 1993; Stanke *et al* 1998). The jets have terminal velocities of hundreds of km s^{-1}, as indicated by both radial velocities and the proper motions of jet features. Recent wide-field imaging of star forming regions has revealed that jets can extend over very large size scales, comparable with the extent of molecular outflows (e.g. Reipurth *et al* 1997). On much smaller size scales, HUBBLE SPACE TELESCOPE (HST) observations of the emission line jets associated with the nearby sources HH30 and DG Tau (Burrows *et al* 1996; Kepner *et al* 1993) demonstrate that the flows are collimated on solar system size scales, within 40 AU of the star.

At the smallest size scales, as probed by high-resolution spectroscopy, are dense, high-velocity (hundreds of km s^{-1}) winds which produce the strong blueshifted absorption features in the profiles of lines such as Hα and Na I D (e.g. L1551—Mundt *et al* 1985; see also Mundt 1984). These wind signatures are observed not only among the young, embedded population but also

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

among more evolved, optically revealed young stars (see 'Disk accretion rates and stellar inflows' below). The densities and temperatures required to excite the hydrogen and Na I D lines strongly favor formation within $\sim 10 R_*$ of the star. When combined with the large velocities of the broad blueshifted absorption features, the implication is that winds are accelerated to high speed within a few stellar radii of the stellar surface. For the most active of the optically revealed young stars, winds are inferred to be cool ($\sim$6000 K) and energetic ($\sim 10^{-7} M_\odot$ yr^{-1}) (e.g. Giovanardi *et al* 1991; Najita *et al* 1996b). The momenta contained in the wind appear sufficient to drive the associated molecular outflows. For example, the dynamical lifetime of molecular outflows (ratio of linear extent to outflow velocity) is typically 10^5 yr. A wind with the above properties blowing for this length of time would provide a momentum input of a few $M_\odot$ km s^{-1} which is comparable with the momentum contained in the associated molecular outflows (cf Levreault 1988). We will return in 'Origin of initial stellar mass and angular momenta' to the origin of winds and jets and their role in the solution of the angular momentum problem for star formation.

Circumstellar disks

Because of the finite angular momentum of molecular cloud cores (e.g. Goodman *et al* 1993), cloud collapse is expected to result in the formation of a circumstellar disk with a characteristic size comparable with that of the solar system. In addition to their role as the reservoir of mass and angular momentum from which stars accrete a substantial fraction of their mass, the likelihood that disks are also the environments in which planets form has led to long-standing interest in their existence and physical properties.

One of the earliest studied and most commonly observed signatures of disks is the infrared excesses that disks contribute to the spectral energy distribution of the young star system owing to the processes of active accretion (e.g. Lynden-Bell and Pringle 1974) and passive reprocessing of stellar light (e.g. Adams *et al* 1987). Simple modeling of disks as a radial sequence of blackbodies weighted by emitting area provides a good fit to spectral energy distributions and implies disk temperatures of thousands of K at a few R_* and temperatures of a few tens of K at 100 AU. If infrared excesses are taken as an indicator of the presence of a disk, disk dispersal times in nearby star forming regions are found to be a few Myr, although with a large dispersion among the sources in a given region (e.g. Kenyon and Hartmann 1995; Hillenbrand and Meyer 1999; Meyer *et al* 1999; figure 2).

While the agreement between spectral energy distributions and the predictions of simple physical models strongly suggests the existence of disks, we need to turn to techniques with greater spatial or spectral resolution in order to confirm their flattened, centrifugally supported nature. The excellent spatial resolution of HST has been used to provide perhaps the best evidence for a flattened, disk-like morphology. WFPC2 observations

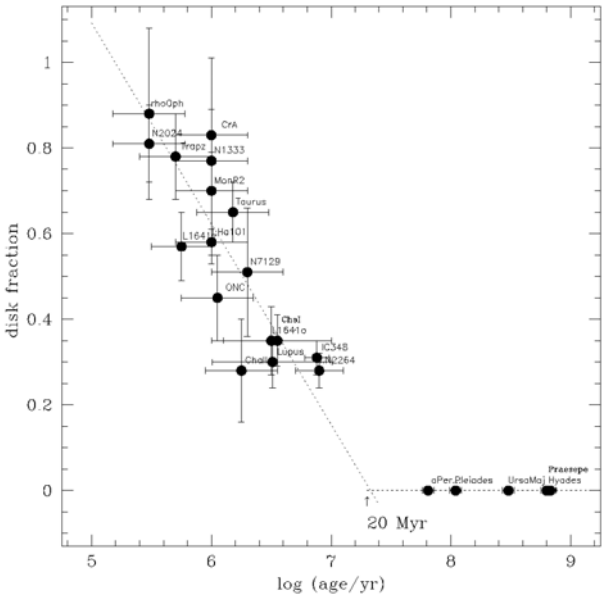

Figure 2. A preliminary result from Hillenbrand and Meyer (1999) which shows the fraction of stars that have disks, as diagnosed by near-infrared excesses, in clusters of different ages. The results appear to indicate that disks disperse on a timescale of <10 Myr.

of systems such as HH 30 (Burrows *et al* 1996) strongly suggest an edge-on disk system where the outline of a flared disk is revealed by scattered stellar light. The sillouette disks in the Orion nebula (McCaughrean and O'Dell 1996) also provide dramatic evidence for cool, dusty, disk-like structures 50–1000 AU in size that are seen in absorption against the bright emission line background of the nebula.

An alternative approach is the use of millimeter and submillimeter interferometry to study the structure and kinematics of disks on solar system size scales ($\sim$50 AU). The subarcsecond angular resolution now achieved by interferometers (e.g. the CSO–JCMT Interferometer[1], the Berkeley Illinois Maryland Association (BIMA) Array and the Very Large Array (VLA) at 7 mm) is well suited to the angular scales of solar system sized disks at the distances of nearby star forming regions ($\sim$150 pc distant). Multiwavelength continuum measurements are used to study the dust emissivity and column density distribution of the disk as a function of radius, from which disk masses can be estimated. For example, using the 40 milliarcsecond resolution of the VLA at 7 mm, Wilner *et al* (1999) showed that the dust surface density distribution of the disk associated with HL Tau has a shallow slope (flatter than $\propto r^{-1}$) over the range $\sim$5–100 AU (figure 3). The inferred mass of the disk is $\sim 0.6 M_\odot$ (e.g. Mundy *et al* 1996).

Disk kinematics at solar system size scales can be probed by interferometric studies of molecular line

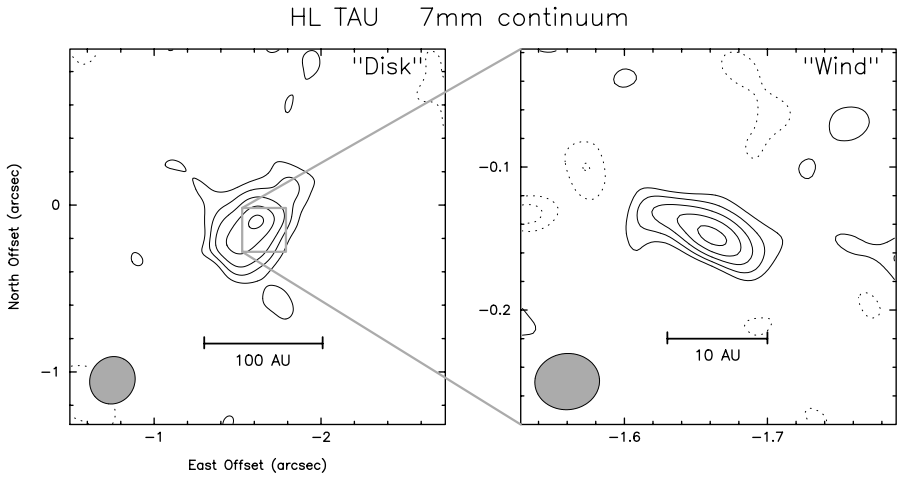

Figure 3. Images of the T Tauri star HL Tau obtained with the VLA at 7 mm with 40 milliarcsecond resolution (Wilner *et al* 1999). The right panel shows the reconstructed image obtained from data taken at baselines longer than 1000 kλ which reveals jet-like emission from an ionized wind. Given the angular scale of the image, this result suggests that jets are collimated very close to the star. The left panel shows a lower-resolution map obtained after subtracting the wind component, which reveals dust emission from a disk. The absence of a steep increase in surface brightness toward the star argues for a surface density distribution that is flatter than $\sim r^{-1}$.

emission at millimeter wavelengths. Such studies typically detect molecular line emission on size scales (∼500 AU) larger than that of the continuum emission. The kinematics of the emitting gas sometimes shows relatively clear evidence for rotation (e.g. Koerner and Sargent 1995), but the signature of radial inflow (e.g. Hayashi *et al* 1993) and/or outflow can often dominate the kinematics, making the detection of rotational motion difficult.

At much smaller size scales ($r < 5$ AU), disks are currently studied using infrared spectroscopy, where high spectral resolution is used in lieu of high spatial resolution to probe disk properties. Because of the high densities and warm temperatures (100–5000 K) of disks within 5 AU, molecules are abundant in the gas phase, and their infrared vibrational–rotational transitions sufficiently excited that molecular spectroscopy in the near- and mid-IR is a powerful probe of disk structure and dynamics. For example, $R = 20\,000$ spectroscopy of 2.3 μm CO overtone emission from young stars reveals a spectral shape that strongly suggests a disk origin (figure 4; Carr *et al* 1993; Najita *et al* 1996a; see also Chandler *et al* 1993). These observations currently provide some of the best evidence for the existence of centrifugally supported structures around young stars.

Disk accretion rates and stellar inflows

The rate of mass accretion through disks can be measured from the excess emission in both the infrared and the optical–UV that the accretion process contributes to the composite spectral energy distribution of the young stellar system. As described in the previous section, the infrared excesses arise in part from the dissipation of gravitational potential energy as disk matter spirals in toward the inner disk boundary (Lynden-Bell and Pringle 1974). While infrared excesses have frequently been used to infer the mass accretion rates of embedded sources, their utility as a measure of the disk accretion rate is compromised by the the fact that other physical processes, such as the reprocessing of stellar light by the disk (e.g. D'Alessio *et al* 1998) and other circumstellar matter (e.g. Natta 1995), also produce infrared excesses which must be accounted for in order to extract an accurate accretion rate.

In comparison, the UV excesses arise from the dissipation of additional gravitational potential energy as disk matter makes its way from the inner disk boundary onto the star. Since the origin of the emission is more uniquely associated with the accretion process, UV excesses can be regarded as a more robust measure of disk accretion rates (e.g. Bertout *et al* 1988; Calvet *et al* 1999). Because UV excesses are difficult to measure except in the case of optically visible accreting stars, i.e. the population known as the classical T TAURI STARS, this section and the next focus more specifically on the properties of these stars. The classical T Tauri stars are in a later phase of evolution than the embedded sources among which molecular outflows and stellar jets are more common (see 'Outflow' above) and are characterized by lower levels of mass accretion and mass loss.

Until the early 1990s, it was believed that circumstellar disks extended essentially up to stellar surfaces and that UV excesses arose from the dissipation of rotational energy as disk matter spun down in a boundary layer to join the slowly rotating star (i.e. a star rotating much below breakup). The hot boundary layer was then believed to produce the Balmer continuum emission and much of the rich emission line spectrum that is characteristic of T Tauri stars. However, the origin of these spectral features has recently been reinterpreted within a physical picture that offers an explanation for both the slow rotation rates of T Tauri stars and the origin of their winds.

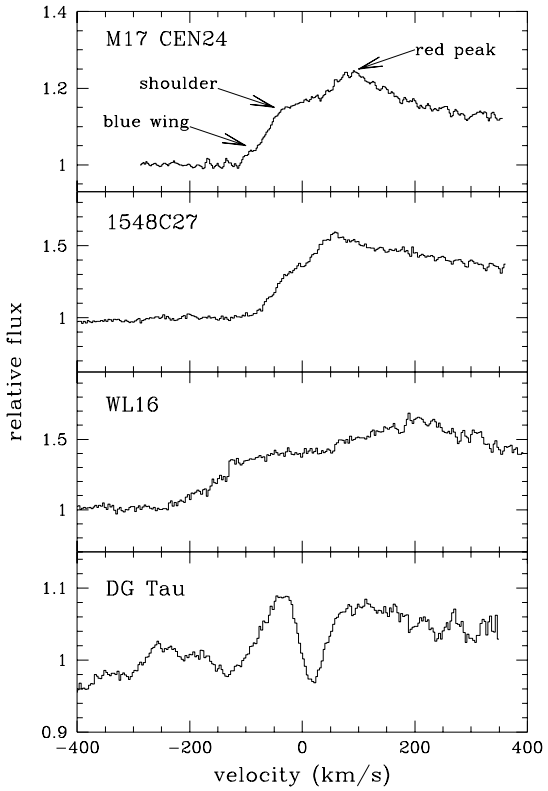

Figure 4. The spectroscopic signature of bandhead emission from a rotating disk (a blue wing, shoulder and red peak) is commonly observed in young stars over a range of masses, from the T Tauri star DG Tau ($\sim 1 M_\odot$), WL 16 ($\sim 2 M_\odot$) and 1548C27 ($\sim 4 M_\odot$), to a high-mass star ($\sim 10 M_\odot$) in the M17 cluster (Carr *et al* 1993; Najita *et al* 1996a; Carr *et al* 1999; Najita *et al* 1999). In the DG Tau spectrum, the signature is less clear owing to strong stellar CO bandhead absorption.

A variety of observations now support the view that accreting disk matter joins the star not through a boundary layer but through accretion along stellar magnetic field lines. Evidence for stellar inflows within a few stellar radii of the star comes from the inverse P Cygni profiles of the upper Balmer lines of some T Tauri stars (Walker 1972) which indicate infall velocities of several hundred km s^{-1}. Further evidence comes from the almost ubiquitous presence of blueward asymmetries in the upper Balmer and Brackett line profiles (Edwards *et al* 1994; Najita *et al* 1996b) which are interpreted as arising in gas infalling onto the star, a situation which results in preferential absorption on the red side of the line profile (cf 'Infall' above). The interpretation that these line profile properties are signatures of magnetic accretion is supported by RADIATIVE TRANSFER models of idealized magnetic accretion flows which reproduce many of the observed line profile features and trends (Calvet and Hartmann 1992; Muzerolle *et al* 1998a,b). In this revised picture, the post-shock gas at the base of the magnetic accretion flow is identified as the source of the optical–UV excess formerly attributed to emission from a boundary layer (Königl 1991; see also Bertout *et al* 1988).

Several other observations support the idea of a close dynamical relationship between stellar inflows and winds. Evidence for stellar inflows in the upper Balmer lines is often observed simultaneously with the signature of mass loss (i.e. P Cygni profiles) at Hα (cf 'Outflow' above; Edwards *et al* 1994). Since excitation considerations require that the hydrogen lines are formed close to the star, these observations provide evidence for the simultaneous presence of winds and stellar inflows within a few stellar radii of young stars. Additional evidence comes from synoptic observations of hydrogen line profiles in T Tauri stars. In the T Tauri star SU Aur, the depths of both a blueshifted absorption component (seen in Hα and Hβ) and a redshifted absorption component (seen in Hβ) are observed to vary at the 3 day rotation period of the star but are 180° out of phase (Johns and Basri 1995). These observations can be explained as the result of the interaction between the disk and a dipole stellar magnetic field that is tilted with respect to the stellar rotation axis (cf figure 15 in Johns and Basri 1995). Because stellar fieldlines bend inward toward the star, favoring inflow, in one region of the magnetosphere, and bend outward, favoring outflow, 180° away in azimuth, the rotation of the magnetosphere at the rotation period of the star can account for the observed period and phase difference.

Yet further evidence, of a more statistical nature, comes from the correlation between wind mass loss rates and stellar and disk accretion rates (Edwards *et al* 1993; Hartigan *et al* 1995). Although the errors associated with the measurements are large, current estimated values for these mass loss and mass accretion rates appear comparable within an order of magnitude. Gullbring *et al* (1998) have reexamined stellar accretion rates implied by the optical–UV spectrum of T Tauri stars in the context of the magnetic accretion scenario and find a broad distribution of accretion rates with a median value of $\sim 10^{-8} M_\odot$ yr^{-1}. Estimates of wind mass loss rates based on the profiles and fluxes of traditional diagnostics such as the hydrogen and Na I D lines (e.g. Calvet 1997; see also Giovanardi *et al* 1991; Najita *et al* 1996b) and optical forbidden line emission (e.g. Hartigan *et al* 1995) also result in a broad distribution averaging $\sim 10^{-9} M_\odot$ yr^{-1} (e.g. Calvet 1997), although there is considerably larger uncertainty associated with these values compared with the estimates for stellar accretion rates. A hypothesis for the simultaneous presence of mass accretion and loss, and their comparable mass flux rates, is presented in 'Origin of initial stellar masses and angular momenta' below.

Stellar rotation

The rotation rates of young stars are measured both from the rotational broadening of stellar photospheric absorption lines and from the observation of periodic photometric variability. The latter is attributed to rotational modulation of the stellar flux by the presence of hot or cool spots on the stellar surface. While cool

spots are believed to be the equivalent of large sunspots, the hot spots are now interpreted as arising from the non-axisymmetric components of stellar inflows (Bertout *et al* 1988, 1996; see 'Disk accretion rates and stellar inflows' above). A multitude of rotational broadening and photometric variability studies have shown that the rotation rates of classical T Tauri stars are low, typically much less than the breakup rotation rate, $v \sin i \sim 15$ km s^{-1} or $\Omega_* \sim 0.1\Omega_{\rm breakup}$ (e.g. Vogel and Kuhi 1981; Hartmann and Stauffer 1989; Bouvier *et al* 1993). This result might be considered surprising since these stars are actively accreting, and the accretion of high angular momentum material from a disk might be expected to spin the star to breakup speed.

An important clue to the reason for the slow rotation rates of classical T Tauri stars came from the discovery that these stars, which possess circumstellar disks, rotate more slowly than stars of similar spectral type and age (the weak T Tauri stars) that show no evidence for circumstellar disks (Edwards *et al* 1993; Bouvier *et al* 1993; Choi & Herbst 1996). In these studies, classical T Tauri stars were found to have rotational periods in a fairly narrow range about ∼8 days, while weak T Tauri stars were found to have a mean period 2–4 times smaller. These results were interpreted as evidence that, in the T Tauri phase, stellar angular momenta are regulated by the presence of a disk, presumably through a kind of magnetic coupling between the stellar field and the inner circumstellar disk (Königl 1991; Shu *et al* 1994; Cameron and Campbell 1996; Armitage and Clarke 1996).

While the different theories describing this process disagree in their treatment of the radial extent of the coupling region and the nature of the angular momentum redistribution that allows continued slow stellar rotation, all of the theories share the idea that through disk coupling the star continues to rotate slowly even as it accretes some high angular momentum material from the disk and contracts toward the main sequence. In the context of this picture, the timescale for disk dispersal, and the consequent cessation of disk coupling, is an important factor in setting initial stellar angular momenta. Some degree of variation in initial stellar angular momenta would then appear to be expected, even at ages of a few Myr, given the known dispersion in disk dispersal times, as based, for example, on the intermixed distributions of classical and weak T Tauri stars in the HR diagram for the Taurus star forming region (Kenyon and Hartmann 1995).

These ideas have interesting implications when placed in the context of studies of stellar angular momentum evolution over Gyr timescales. For example, in figure 5 from Bouvier *et al* (1997a), the rotation rates of classical and weak T Tauri stars in Taurus are compared with those of post-T-Tauri stars in Taurus (10–40 Myr old), and stars in the αPer (50 Myr), Pleiades (100 Myr) and Hyades clusters. If interpreted as a pure evolutionary trend, these results might be taken to indicate that on average stellar rotation increases with age owing to stellar contraction until ∼100 Myr, then decreases with age owing to the increasing importance of angular momentum loss in a magnetic solar-type wind (e.g. Bouvier *et al* 1997b). The large breadth of the rotational distribution that is seen at all ages can then be interpreted largely as the result of a dispersion in disk dispersal times (e.g. Bouvier *et al* 1997a), i.e. a spread in initial stellar angular momenta rather than dispersion introduced through subsequent stellar evolution. (See Keppens *et al* (1995) for a somewhat different view.)

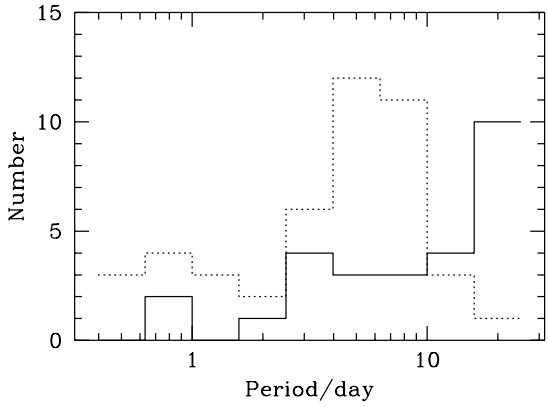

Figure 5. Distribution of rotation periods for stars in the young cluster NGC 2264 (Makidon *et al* 1999). Although stars with disks (solid line) generally rotate slower than stars without disks (dotted line), the distribution of both populations is quite broad.

One of the potential difficulties with this picture is that, in order to explain the population of slow rotators at ages of ∼50 Myr, disks must persist much beyond 10 Myr, and stars must couple effectively to them, in a fair fraction of systems. This seems rather unlikely given that disk dispersal times for T Tauri stars appear to be much shorter (see 'Circumstellar disks' above). Other questions for the future include issues such as whether the initial conditions imposed by molecular clouds (e.g. cloud angular momenta, infall accretion rate) and the effects of early dynamical evolution (e.g. development of close companions) are sufficiently homogenized during the epoch of disk coupling that observations of different clusters and associations can be thought to represent a purely time-dependent sequence.

As a final caveat, it is interesting to note that the study of rotational periods in other star forming regions (e.g. NGC 2264) may end up altering somewhat our picture of rotation rates at early times. Using synoptic observations that are sensitive to a broad range of rotation periods, Makidon *et al* (1999) find a broad period distribution with a significant population of both slow ($P_{\rm rot} \sim 30$ days) and fast ($P_{\rm rot} < 1$ days) rotators at ages of ∼3 Myr. While they confirm the trend that stars with disks rotate slower on average than stars without disks, the period distribution for both populations is quite broad (figure 5). Whether and how such observations fit into our understanding of the rotational evolution of stars is an interesting issue for the future.

Stellar magnetic fields

As indicated in the previous sections, the processes of stellar accretion and angular momentum loss appear to be closely tied to the strength and geometry of stellar magnetic fields at early evolutionary times. Magnetic activity among the T Tauri stars has long been suspected based on a variety of observations including strong x-ray and non-thermal radio emission and photometric evidence for large starspots. One of the most exciting recent developments in this field is the detection of hard x-ray emission from the much younger protostellar population (Koyama *et al* 1996). In this case, hard x-ray emission was used to penetrate the large column densities toward protostars ($A_v \sim 100$) in order to probe the region close to the stellar surface. This result indicates that stellar magnetic activity begins very early in the evolution of low-mass stars.

Exciting progress has also been made in the direct measurement of stellar field strengths and geometries. Measurements of stellar magnetic field strengths in T Tauri stars are complicated by the rotational broadening of the photospheric lines (see 'Stellar rotation' above) which typically exceeds Zeeman broadening at optical wavelengths. For this reason, studies in the optical have ignored line profiles and instead used the enhancement in equivalent width that results from Zeeman broadening as a more indirect measure of stellar field strength. To date, field strengths ~1–2.5 kG have been measured for a few T Tauri stars using this approach (e.g. Basri *et al* 1992). The more direct detection of kilogauss strength fields through the study of Zeeman-broadened line profiles can be made by going to longer wavelengths where Zeeman broadening ($\propto\lambda^2$) dominates over rotational broadening ($\propto\lambda$). Using this approach, a clear signature of Zeeman broadening has been detected in the Zeeman-sensitive Ti I λ2.2 μm line in the spectrum of the classical T Tauri star BP Tau (Johns-Krull *et al* 1999b; figure 6). The average field strength implied by the line profile is 3.3 kG which is in excellent agreement with stellar field values required by theories of magnetic accretion (e.g. Königl 1991; Shu *et al* 1994; Cameron and Campbell 1996; see 'Disk accretion rates and stellar inflows' above).

Several other observations support the existence of an organized component to these strong fields. For example, our ability to measure photometric variability due to the rotational modulation of hot or cool spots (see 'Stellar rotation' above) indicates the existence and long-term stability of an organized magnetic field component. An exciting recent development in the study of the magnetic field geometry of young stars comes from spectropolarimetric studies of certain T Tauri star emission lines. In the classical T Tauri star BP Tau, the He I λ 5876 emission line is strongly polarized and the wavelength shift between the left- and right-circularly polarized components of the line profile implies a field strength ~2.4 kG (Johns-Krull *et al* 1999a; figure 7). Since the He I line is believed to originate at the base of the magnetic accretion flow onto the star, these observations provide clear evidence for a strong, organized field that is associated with accretion onto the stellar surface. Such strong, globally organized fields are necessary if the star is to couple magnetically to a disk several stellar radii away and participate in the processes of stellar accretion and angular momentum regulation.

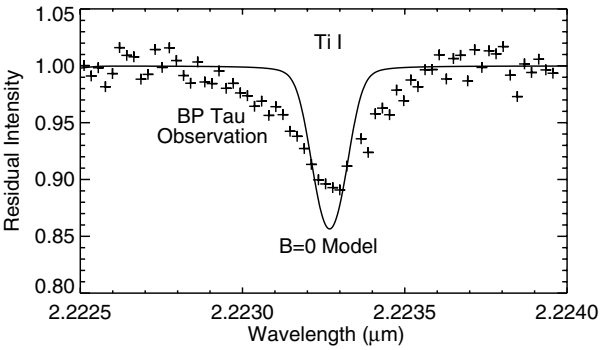

Figure 6. Detection of Zeeman broadening in the Ti I λ2.2 μm line in the spectrum of the classical T Tauri star BP Tau (Johns-Krull *et al* 1999). The Ti I line (plus signs) is found to be significantly broader than a Zeeman-insensitive photospheric line (solid curve). Modeling of the Ti I line indicates a distribution of field strengths on the stellar surface (1–10 kG) with a mean field of ~3.3 kG.

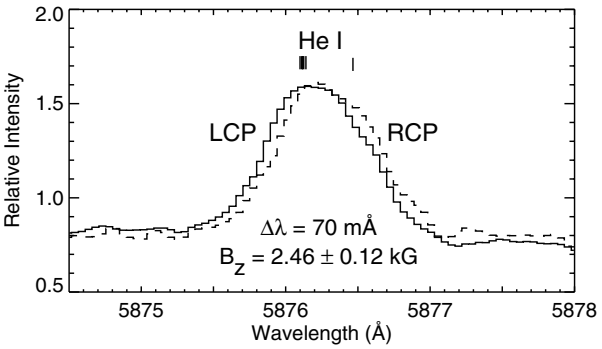

Figure 7. Detection of circular polarization in the He I λ 5876 emission line in the spectrum of the classical T Tauri star BP Tau (Johns-Krull *et al* 1999a). The wavelength shift between the right- and left-circularly polarized components indicates a field strength of 2.46 kG. Since the He I line is believed to form in the base of the magnetic accretion flow, these observations argue that organized fields are associated with accretion onto the stellar surface.

Origin of initial stellar masses and angular momenta

Remarkably, a large fraction of the observations described in the previous sections support and/or find a common explanation within our current understanding of how low-mass stars acquire their initial STELLAR MASSES and angular momenta. A possible synopsis of the story might be as follows. Mass and angular momentum are accreted from molecular clouds in a phase of dynamical infall.

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

(Following an extended observational search, compelling evidence for this phase of evolution has been obtained; see 'Infall' above.) The finite angular momentum of infalling cloud material leads to the formation of a circumstellar disk. (Following another observational search, compelling morphological and kinematic evidence for centrifugally supported structures has been obtained; see 'Circumstellar disks' above.) As a result of disk angular momentum transport, disk matter spirals in toward the star. The star accretes mass and angular momentum from the disk, producing a rapidly rotating star. Rapid rotation coupled with the fully convective STELLAR INTERIOR leads to the production of a strong stellar magnetic field. (We now have good evidence for strong, organized stellar fields and the early onset of magnetic activity; see 'Stellar magnetic fields' above.)

In the picture of Shu *et al* (1994; see also Shu *et al* 1999; Königl 1991; Arons 1986; Camenzind 1990; Shu *et al* 1988) that describes the interaction of the stellar magnetic field with the disk, the stellar field truncates and couples to the disk at a distance, typically a few stellar radii, that depends on disk accretion rates and stellar parameters including the magnetic field strength (figure 8). As a result of the magnetic disk coupling, the stellar rotation rate is slowed and regulated so that it equals the rotation rate at the disk truncation radius (cf Shu *et al* 1997). For typical T Tauri disk accretion rates, stellar parameters and the mean ($\sim$8 day) period of classical T Tauri stars, stellar field strengths of a few kilogauss are required, in good agreement with measured values.

In the Shu *et al* picture, disk accretion pinches the stellar magnetic field at the truncation radius, producing a magnetic geometry that favors dynamically the generation of magnetic accretion flows and winds from the truncation region. Thus, disk matter reaching the inner disk radius can be channeled into either an accretion flow onto the star or into an outflowing wind, providing an explanation for the observed simultaneous presence of stellar accretion flows and winds within a few stellar radii of the star (see 'Disk accretion rates and stellar inflows' above). The back torque of the wind and magnetic accretion flows on the magnetic field footpoints in the disk truncation region act to maintain the pinched magnetic field in the truncation region.

The magnetocentrifugal action resulting from the combination of strong stellar fields and the rapid rotation of the disk (or star) is capable of driving cool, massive winds with terminal velocities and mass loss rates that are in good agreement with the properties of winds from T Tauri stars (and embedded protostars), as described by Najita and Shu (1994). The magnetocentrifugally driven winds play an important role in the solution of the angular momentum problem for star formation. They remove significant angular momentum from the young star system, which allows the star to continue to rotate slowly despite ongoing accretion. For T Tauri stars, the observed kilogauss-strength fields are capable of removing sufficient angular momentum that the wind mass loss rate is a comparable fraction of the disk and stellar accretion rates ($\dot{M}_{\rm W}/\dot{M}_{\rm D} = 0.1$–$0.3$; $\dot{M}_* = \dot{M}_{\rm D} - \dot{M}_{\rm W}$) in reasonable agreement with observationally derived ratios (see 'Outflow' above).

At distances of tens of parsecs, the wind collimates magnetically into a jet embedded in a wider-angle wind (Shu *et al* 1995), in good agreement with HST observations of jet collimation distances. The wind and jet together sweep up the surrounding molecular cloud material, creating a molecular outflow (see 'Outflow' above). At the same time, the outflowing material acts to halt further infall, thereby limiting the mass of the star. At some later time, the disk disperses. The star and disk are consequently decoupled, and the star is free to spin up as it contracts. This picture, as it currently stands, provides a viable framework for understanding the origin and interrelation of many of the observed phenomena associated with young stars and their role in the origin of the initial masses and angular momenta of low-mass stars.

Unsolved problems

Despite the success of the above picture, there are numerous issues that remain to be addressed, including several basic aspects of this picture. For example, it is as yet unclear theoretically whether the magnetic interaction between the star and disk is likely to be time steady or not. Various recent simulations (Hayashi *et al* 1996; Goodson *et al* 1997; Miller and Stone 1997) suggest that the interaction is much less quiescent than in the Shu *et al* (1994) picture. Observational evidence for time-dependent behavior may be uncovered in synoptic observations of T Tauri line profiles which are notoriously variable.

Another important issue is the origin of angular momentum transport in disks. Gravitational instabilities are efficient when the circumstellar disk mass is a fair fraction of the stellar mass, a situation which may be relevant at early times. In the T Tauri phase, where disk masses appear to be too low to support significant gravitational instabilities, magnetic instabilities such as the Balbus–Hawley instability (Hawley *et al* 1995) appear to be the most promising.

Our understanding of the stellar rotational properties of young stars is still in its early stages, despite several conclusions having already been drawn from the existing data. From an observational perspective, observations of large numbers of stars will be needed to study rotation as a function of mass and age and to average over the differences that may be inherent in trying to compare stars with different formation histories (e.g. molecular cloud initial conditions, etc). Various groups are currently engaged in expanding the original work on young stars in the Taurus and Orion regions to a larger number of stars and clusters. These results are eagerly awaited.

As discussed above, the longevity of inner accretion disks may be an important issue for the understanding of the origin of slow rotators and the spread in stellar angular momenta that exists in 10–100 Myr old clusters. The factors

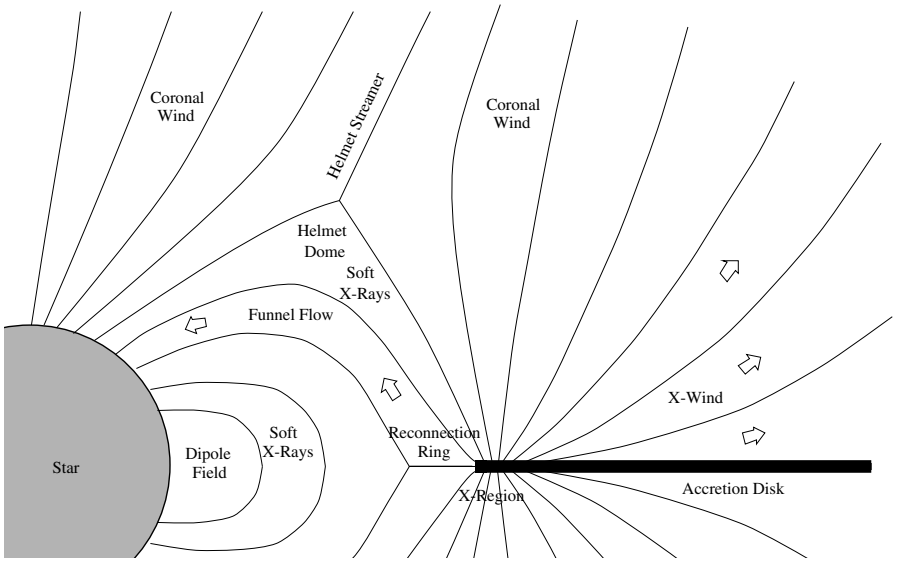

Figure 8. Schematic drawing of the X-wind model (Shu *et al* 1994, 1999). In the interaction between a stellar dipole magnetic field and a surrounding accretion disk, the disk is truncated and the magnetic configuration of the star (thin lines) is altered, allowing mass inflow onto the stellar surface in magnetic accretion flows, and energetic mass loss in a magnetocentrifugal wind.

that control disk dispersal are at present unclear, although some of the relevant processes have been identified. For example, since disk structure is known to be affected by the presence of stellar companions (e.g. Mathieu 1994), the longevity of inner disks may similarly be affected by the presence of close stellar or planetary companions.

Another generic issue is the extent to which this picture, developed to explain the formation of isolated, low-mass stars, applies to stars in clusters and/or to stars of higher masses. It may be necessary to consider other physical processes (e.g. fragmentation, mergers of stars and/or clouds) in order to understand the origin of stellar masses and angular momenta in dense clusters. Further work is needed to understand these processes.

On the issue of the applicability of this picture to high-mass stars, an issue that also remains unresolved, there is some observational evidence that suggests that similar physical processes may be involved. High-resolution spectroscopy of the CO overtone emission from a high-mass star in the young cluster M17 has revealed the spectral shape of emission from a rotating disk, providing kinematic evidence for disks around young high mass stars (Najita *et al* 1999; figure 3). This indicates that stars may evolve from low to high mass by accretion through disks (e.g. Palla and Stahler 1993). These observations also support the view that radiation pressure is not a barrier to the formation of high-mass stars and that consequently the high end of the stellar initial mass function should be independent of metallicity, as is observed (Massey *et al* 1995).

Acknowledgments

I am very grateful to Neal Evans, Lynne Hillenbrand, Michael Meyer, David Wilner, Steve Strom, Russ Makidon, Jeff Valenti, Chris Johns-Krull and Frank Shu for providing illustrations for this review.

Star Formation and Radio Emission from Normal Galaxies

The radio continuum properties of normal DISK GALAXIES are shaped primarily by STAR FORMATION. This article reviews the relationship between the radio continuum emission and the star formation process in normal SPIRAL and IRREGULAR GALAXIES. The most common tracers of global star formation in external galaxies are optical emission lines and far-infrared (FIR) continuum emission. The former arises from photoionized gas while the latter is from dust grains heated by stellar photons. One component of radio continuum emission is thermal bremsstrahlung emitted by the same photoionized plasma that produces the optical emission lines. If that were the only source of radio emission one would expect a strong correlation between, say, Hα and the radio continuum. However, except for the highest frequencies the radio continuum emission is dominated by SYNCHROTRON RADIATION emitted by relativistic electrons gyrating in magnetic fields so that any correlation between thermal radio emission and Hα is easily obscured. Surprisingly, the strongest correlation is that between the FIR and the nonthermal radio continuum. The most likely explanation for the correlation is that star formation drives both forms of emission. Within this scenario lie two fundamental mysteries: (i) why is the FIR–radio correlation one of the strongest in astrophysics? (ii) what is the connection between star formation and the production of cosmic rays? This article focuses on the physical underpinnings of these problems. In the process, the relationship between star formation and radio emission is fully explored.

Historical overview

By the end of the 19th century it was well known that there existed a background level of highly penetrating radiation. The issue of whether this radiation emanated from the Earth or from space was a matter of considerable debate and was not settled until a daring experiment by the Austrian physicist Victor Hess in 1912. Hess piloted a balloon to a height of 5 km and recorded the radiation flux as a function of altitude. His measurements showed a steady increase in flux with altitude, proving their 'cosmic' origin. The term 'COSMIC RAYS' was born because at the time it was believed that cosmic rays were photons similar to γ-rays but with greater penetrating power. Their particle nature was uncovered by Bothe and Kolhorster in 1929 using coincidence techniques. By this time, however, the term 'cosmic ray' had stuck and remains in use today.

Even after the recognition that cosmic rays were particles of an extraterrestrial origin, their distribution in space remained unknown. The cosmic rays appeared to arrive from all directions with equal likelihood. Their isotropic distribution shed little light on their origin indicating only that the cosmic ray particles are heavily scattered before reaching the Earth. Though RADIO ASTRONOMY was born in 1935 through the work of Karl Jansky, no connection with cosmic rays was made until it was realized, many years later, that Galactic radio emission is, in fact, synchrotron radiation emitted by cosmic ray electrons.

In the 1940s Grote Reber mapped the distribution of radio emission and showed that it closely followed the Milky Way plane (e.g. Reber 1940). This led to the suggestion that the radio emission was associated with stars. This was probably the first step in connecting star formation to radio emission. However, it was quickly realized that the thermal emission of normal stars would fall well short of the observed level of radio emission. The radio emission was shown to have a nonthermal spectrum. A special class of 'radio stars' was therefore proposed. In 1950, Alfvén and Herlofson proposed that relativistic particles in the atmospheres of these radio stars produced radio emission via the synchrotron mechanism. Kiepenheuer (1950) generalized the idea to broadly distributed cosmic ray electrons and magnetic fields in the interstellar medium (ISM). As it turned out Kiepenheuer's idea was correct (although it took another 10 yr to be accepted) but Alfvén and Herlofson's origin idea proved not to be viable.

The connection between cosmic rays and Galactic radio emission was fully cemented in the review paper by Ginzburg and Syrovatskii in 1965. Thus, some 50 yr had passed since the discovery of cosmic rays and some 30 yr since the advent of radio astronomy before the two were linked and it was realized that cosmic rays fill the Milky Way Galaxy.

The connection between radio emission and star formation has not been an easy one to establish. Fritz Zwicky was the first to propose that SUPERNOVAE provide the needed link (Zwicky 1939). The currently favored view is close to Zwicky's original insight.

The most favored hypothesis of the origin of cosmic rays combines SUPERNOVA REMNANTS (SNRs) with the theory of diffusive shock acceleration (DSA) (e.g. Bell 1978; Axford 1981; Drury 1983; Blandford and Eichler 1987; Jones *et al* 1998). A supernova explosion is believed to typically release in excess of 10^{51} erg of energy much of which is carried by the subsequent SNR in the form of kinetic energy. The rapid expansion of the SNR causes the SNR to couple with the ISM through a supersonic shock. According to the DSA theory, particles can be accelerated at the shock front to cosmic ray energies. It is this coupling which allows the SNR to convert some of its kinetic energy into relativistic particles.

It is now well established that all disk galaxies have relativistic cosmic ray gas as a major constituent and that this gas plays an important role in the chemical and kinematical evolution of individual galaxies. In our Galaxy, the relativistic gas contributes as much energy density as the interstellar magnetic field and the thermal gas (table 1). This equipartition of energies is probably a feature of most disk galaxies (e.g. Duric 1988). In table 1, the various phases of the ISM are shown (including the cosmic rays), along with recent estimates of their filling

Table 1. Components of the ISM.

Phase	f	n (cm^{-3})	kT (eV)	nkT (eV cm^{-3})
Molecular clouds	10^{-3}	>100	$<10^{-2}$	–
Cold neutral medium	0.025	40	$\approx 10^{-2}$	≈ 0.4
Warm neutral medium	≈ 0.5	≈ 0.5	≈ 1	≈ 0.5
Warm ionized medium	≈ 0.25	≈ 0.2	≈ 1	≈ 0.2
Hot ionized medium	≈ 0.2	$\approx 3 \times 10^{-3}$	$\approx 10^2$	≈ 0.3
Cosmic rays	≈ 1	$\approx 10^{-9}$	$\approx 10^9$	≈ 1

factor, f, the number density, n, the thermal energy per particle and the energy density.

Although the relativistic gas contains a mix of nuclei, electrons and other more exotic particles, it is the electrons that produce all the observable synchrotron radio emission, the same emission seen by Jansky and Reber in the case of our Galaxy. This radiation mechanism dominates the radio continuum spectra of spiral and irregular galaxies for wavelengths longer than about 1 cm.

Star formation plays a much broader role in shaping the integrated properties of galaxies. An appreciation of this broader picture is necessary in order to understand fundamentally important observations such as the radio–infrared correlation of galaxies and to define the tools needed to study the details of the relationship between star formation and radio emission of galaxies.

The basic picture

It is now generally accepted (although not proven) that star formation drives the radio–FIR correlation and that it also accounts for a (somewhat weaker) correlation between Hα and radio emission. A schematic view of this scenario is presented in figure 1. The essential points are that (i) photons from the young massive stars photoionize surrounding gas which gives rise to emission line radiation and thermal bremsstrahlung, (ii) massive stars heat dust grains which in turn radiate in the FIR and (iii) the same stars quickly become supernovae, producing remnants that accelerate the cosmic ray electrons which in turn give rise to nonthermal radio emission.

According to figure 1, of all the radiative processes shown, synchrotron emission is the most removed from the young stars (it is at the endpoint of the longest of the three arms in the schematic). In order for the FIR and radio emission to be tightly correlated, for example, it is necessary for the SNRs to play a direct and dominant role in converting stellar energy into relativistic particles.

We now describe the radiative processes along each of the three arms shown in the schematic. We confine our discussion to the radiation mechanisms associated with recently formed stars as opposed to the processes that operate during pre-main-sequence evolution since it is the young massive stars that appear to drive the radio properties of galaxies.

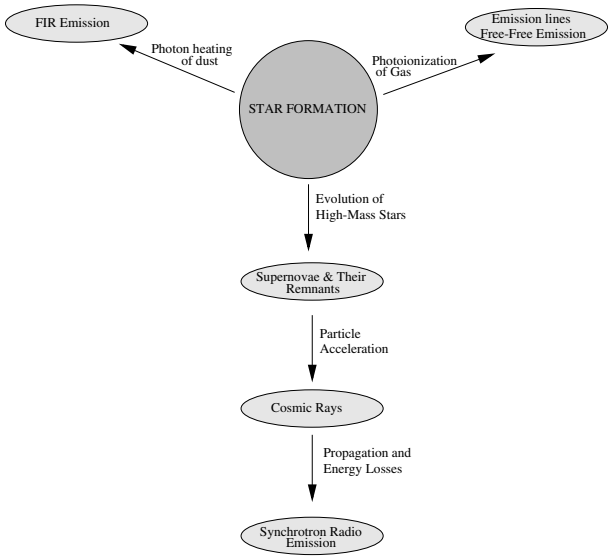

Figure 1. The currently favored scenario for explaining the connection between star formation and the radio emission. The relevant radiation mechanisms are noted.

Photoionization

Stromgren (1939) first proposed that hot, luminous stars should ionize the gas around them and form what we now call H II regions. The more luminous, massive stars evolve very quickly such that their evolutionary time scales can be shorter than the time scale of star formation for a given star forming region. The presence of such luminous stars and their associated H II REGIONS therefore marks regions of recent and ongoing star formation. The detection of H II regions is therefore synonymous with tracing star forming regions.

For an H II region in ionization balance, the ionization rate is balanced by the recombination rate so that (Shu 1991)

$$\dot{N}_{\rm i} = 3 \times 10^{-13} n_{\rm e}^2 V \ {\rm s}^{-1}$$

where $\dot{N}_{\rm i}$ is the ionization rate in photons per second, $n_{\rm e}$ is the density of the ionized gas and V is the volume of the H II region. It is this relationship that establishes the size of an H II radius (via V) for a given ionizing rate.

Free–free radiation. The ions and electrons in the ionized gas undergo Coulomb interactions which lead to thermal

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

bremsstrahlung or free–free radiation (sometimes referred to as thermal radio emission). At radio frequencies, the free–free radiated power from an H II region is given by (Tucker 1975)

$$L_\nu^{\rm ff} = 7.3 \times 10^{-39}\, n_{\rm e}^2 V \frac{\nu^{-0.1}}{5\,{\rm GHz}}$$

for an assumed temperature of 10^4 K. Note the relatively flat spectrum compared with the steeper spectrum associated with synchrotron radiation.

The relationship between the 6 cm radio power and the ionizing luminosity is given by combining the above equations, yielding

$$L_\nu^{\rm ff} = 2.4 \times 10^{-26} \dot{N}_{\rm i}\ {\rm erg\ s^{-1}\ Hz^{-1}} \frac{\nu^{-0.1}}{5\,{\rm GHz}}.$$

Emission line radiation. A similar relationship exists between the Balmer line fluxes and the ionization flux. In the case of the Hα line luminosity,

$$L_{{\rm H}\alpha} = 1.3 \times 10^{-12} \dot{N}_{\rm i}\ {\rm erg\ s^{-1}}.$$

Imaging of galaxies in the light of Hα has become a common method for tracing global star formation in external galaxies. It should be noted that all kinds of emission lines are produced by H II regions. The most common types of lines are recombination lines (such as the Balmer series, including Hα) and collisionally excited lines from atoms having low-lying energy states. These are generally forbidden lines such as the 4995, 5007 Å doublet of O III. However, in most instances, the Hα is the strongest and therefore easiest to detect.

The properties of an H II region are determined by the nature of the embedded star and the density and composition of the surrounding medium. Table 2 summarizes some basic properties of H II regions ionized by various stars. The first column indicates the spectral type of the main sequence star responsible for ionizing the H II region. The corresponding ionizing, free–free and Hα luminosities are shown in the other three columns.

Table 2. Radiative properties of H II regions.

Spectral type	$\log \dot{N}_{\rm i}$	$L_\nu^{\rm ff}$(erg s^{-1} Hz^{-1})[a]	$L_{{\rm H}\alpha}$(erg s^{-1})
O5	50.0	2.4×10^{24}	1.3×10^{38}
B0	48.7	1.2×10^{23}	6.5×10^{36}
A0	42.7	1.2×10^{17}	6.5×10^{30}

[a] Evaluated at 5 GHz.

Hα and free–free emissions can both be used to trace star forming regions in galaxies. The former has the advantage that it can be readily detected with great efficiency to very faint levels. However, unlike the radio emission the Hα emission is attenuated by dust. The thermal free–free radio emission therefore represents a more direct measurement of the ionizing flux. The drawback to the radio method is that the emission is quite weak, thereby limiting the number of H II regions that can be detected relative to the Hα method. For example, an H II region from a B0 star would have a flux density of only about 0.1 mJy, barely detectable at the 3σ level with the VLA. Hα emission, on the other hand, can be detected much more easily from the same H II region. The use of Hα to study star formation is therefore quite common. Studies of free–free emission are now possible but only for the nearest galaxies, using the VLA (e.g. Devereux *et al* 1997). However, neither approach is completely satisfactory.

FIR emission

The dust grains that fill the disks of normal galaxies are heated primarily by stellar photons. A good fraction of these photons are nonionizing photons and leaked ionizing photons from recently formed stars. The exact fraction that can be attributed to young, massive stars is the subject of considerable debate. However, it is generally agreed that star formation generates a significant enough portion of the dust heating that the resulting FIR emission can be used as an indicator of global star formation.

The stellar radiation heats dust grains to temperatures of 15–30 K. At these temperatures the dust re-radiates emission in the FIR, mainly between about 25 and 200 μm. The dust acts as a bolometer, accurately measuring the energy it absorbs.

The FIR luminosity between 40 and 1000 μm can be estimated from measurements at the standard IRAS bands of 60 and 100 μm using the formula

$$L_{\rm FIR} = 6.0 \times 10^5 \left(2.58 \frac{S_{60}}{\rm Jy} + \frac{S_{100}}{\rm Jy}\right) \left(\frac{d}{\rm Mpc}\right)^2 L_\odot$$

which typically represents over 80% of the bolometric IR flux (2–1000 μm). A major advantage of FIR emission over Hα in tracing star formation is its relative immunity to extinction and that it measures much of the bolometric luminosity emanating from the star forming regions. A major drawback is the limited sensitivity to surface brightness and relatively poor angular resolution offered by FIR instruments. However, this field promises to leap forward with the launching of SIRTF, a new high-resolution, high-sensitivity IR telescope.

Synchrotron emission

According to the model shown in figure 1, SNRs accelerate electrons to relativistic energies. A single relativistic electron emits radiation whose intensity and spectral properties are determined by the kinetic energy of the electron and the strength of the magnetic field in which it is gyrating. The shape of the spectrum, $J(\nu, E)$, is given by

$$J(\nu, E)\,{\rm d}\nu = \frac{\sqrt{3}e^3}{mc^2} B \sin\theta \frac{\nu}{\nu_{\rm c}}\,{\rm d}\nu \int_{\nu/\nu_{\rm c}}^{\infty} K_{5/3}(\eta)\,{\rm d}\eta \qquad (1)$$

where ν is the frequency of the emitted radiation, E is the kinetic energy of the electron, B is the strength of the magnetic field, θ is the angle between the instantaneous velocity vector of the electron and the magnetic field, m is the mass of the electron and $K_{5/3}$ is a modified Bessel function. The quantity ν_c is commonly referred to as the critical frequency and is given by

$$\nu_c = \frac{3e}{4\pi mc} B \sin\theta \frac{E^2}{m^2c^4} \tag{2}$$

where the dependence on the electron energy, E, is now explicit. The critical frequency is closely related to the frequency of the peak of the spectrum, ν_{max}, such that $\nu_{max} = 0.3\nu_c$. In typical interstellar magnetic fields, relativistic electrons radiate in the radiofrequency portion of the electromagnetic spectrum.

Integration of equation (1) over all frequencies (e.g. Shu 1991) yields the total power radiated by a highly relativistic electron,

$$\langle P \rangle = \frac{1}{6\pi} \frac{E^2}{m^2c^4} c\sigma_T B^2 \tag{3}$$

where $\langle P \rangle$ indicates a statistical average expected from an isotropic distribution of θ and $\sigma_T = 8\pi e^4/3m^2c^4$ is the Thomson cross section.

It is interesting to note the mass dependence in equations (2) and (3). The critical frequency and the radiated power are both very strong functions of the mass. It is easy to see that only electrons contribute significantly to the synchrotron emission in a typical galactic environment. Ions are simply too heavy to contribute significantly to the radio emission of a galaxy.

The synchrotron radiation we see from a galaxy arises from an ensemble of electrons following some energy distribution $n(E)$. With equation (3) we can define a volume emissivity

$$\rho j_\nu = \int_{mc^2}^{\infty} \langle P_\nu(E) \rangle n(E)\, \mathrm{d}E. \tag{4}$$

Direct observations of cosmic rays near the Earth suggest that

$$N(E)\, \mathrm{d}E = N_0 E^{-p}\, \mathrm{d}E \tag{5}$$

with $p \approx 2.5$. Now substituting equations (3) and (5) into equation (4) and integrating over frequency and volume (assumed homogeneous) yields (Pacholczyck 1970) the luminosity of an ensemble of electrons:

$$L_\nu = \int_V \rho j_\nu\, \mathrm{d}V \propto N_0 B^{(p+1)/2} \nu^{-(p-1)/2}.$$

where N_0 is the number of cosmic ray electrons in the source volume. It is clear from the above that the spectrum is a power-law spectrum with an index

$$\alpha = \frac{p-1}{2}$$

so that

$$L_\nu \propto N_0 B^{1+\alpha} \nu^{-\alpha}.$$

Observations of normal galaxies indicate that α is universally around 0.75. These numbers indicate that the electrons follow an energy distribution that is also a power law, consistent with the observed energy distribution of cosmic rays near the Earth. The universality of the electron energy distribution among normal galaxies suggests that cosmic rays may be accelerated by a common mechanism. In other words, whatever is found to work for one disk galaxy may apply to all galaxies, including our own.

It is interesting to note that nothing in the above equations directly relates to the young stellar content of a galaxy.

The link between star formation and radio emission

It is clear, from the above discussion, that the FIR, emission line radiation and free–free emission can be used to directly trace the recently formed stars in galaxies. Similarly, nonthermal radio emission (synchrotron radiation) can be used to trace the cosmic ray electrons. Consequently, the link between star formation and the production of cosmic rays (the bottom arm in figure 1) is best studied by comparing FIR, emission line and radio data of galaxies.

Figure 2 shows a 60 μm and a 6 cm image of M33 smoothed to the same resolution. Note that the radio–FIR correlation appears to hold even inside galaxies. It is clear that some form of a relationship must exist between star formation, traced by the FIR emission, and the relativistic electrons, traced by the radio emission.

As noted above, the link between star formation and radio emission is more complicated than that for the other radiation mechanisms. The chain of events starting with star formation and ending with synchrotron emission is much longer than that required to explain FIR, emission line and free–free emission. The critical link in this chain is the role of the SNRs.

If the SNRs are to be the primary source of cosmic rays they must provide sufficient energy to maintain the cosmic ray population of a galaxy. Thus, there must be a sufficient number of supernovae to be able to continuously replenish the cosmic rays over the duty cycle of the medium. Consider, for example, a cosmic ray medium of a disk galaxy that has an energy (kinetic energy of all the relativistic particles) of 10^{55} erg and which escapes from the disk over a period of 10^7 yr. The energy needed to maintain the relativistic medium is 10^{48} erg yr^{-1}. This requires the energy of 10^4 SN over the duty cycle of the relativistic medium or 1 SN per 10^3 yr. However, it is unlikely that an SN converts all of its energy into relativistic particles. The conversion efficiencies are not known. A conversion efficiency of 1%, for example, would require an SN rate of 1 every 10 yr. Thus, the ability of SNRs to maintain the cosmic ray population depends on the efficiency of cosmic ray production.

Once free of the SNR the newly accelerated electrons and ions diffuse through the ISM, establishing a general

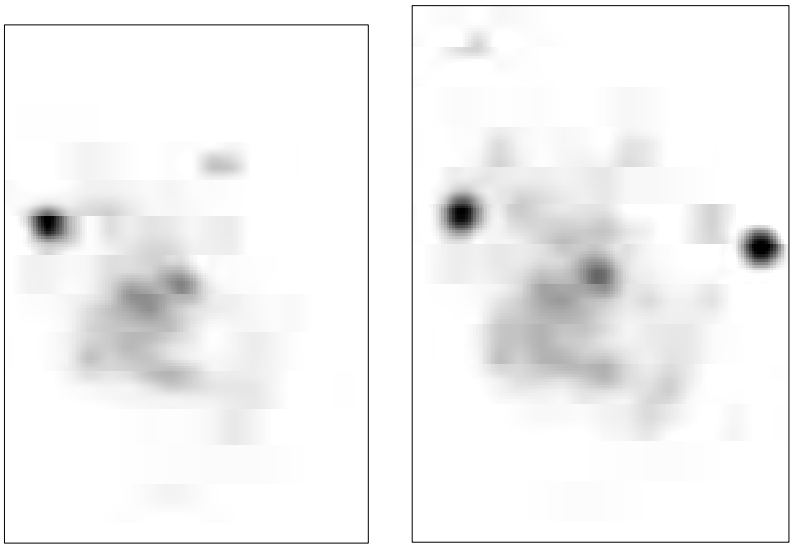

Figure 2. Left: a 60 μm image of M33. Right: a 6 cm image of M33. The left image traces emission from dust heated by young stars. The right image traces relativistic electrons emitting synchrotron radiation. The well-known radio–FIR correlation of galaxies appears to extend to spatially resolved regions of galaxies, thereby strongly strengthening the argument that star formation plays a key role in shaping the radio emission of galaxies. Except for the radio source to the right, the condensations and spirality of the galaxy show similarly in both pictures.

disk distribution of cosmic rays. This relativistic gas forms what is essentially a phase of the ISM. The relativistic phase of the ISM can remain in a steady state configuration because a balance between cosmic ray production and cosmic ray losses (via energy losses and escape) is established when the production and loss rates are equal. Such a balance is exacted when the supernova rate is constant over time scales long compared with the loss time scale.

The maintenance of the cosmic ray gas is accomplished via a continuous injection by a continuously evolving population of SNRs. Consider a simple model in which SNRs are the sole injectors of relativistic particles in the disk of a galaxy. Particles are injected on the time scale of the SNR lifetime, $\tau_{\rm snr}$. Estimates of such a time scale range from 10^4 to 5×10^4 yr (Smith 1991; Woltjer 1972; Gordon *et al* 1998). We adopt a value of 2×10^4 yr in this analysis (corresponding to the oldest SNRs in the Sedov–Taylor phase in the M33 sample; see Smith 1991; Gordon *et al* 1998). The other important time scale is that over which the relativistic medium would dissipate in the absence of new particles. In cosmic ray terms this is the residence time, $\tau_{\rm r}$, of the relativistic particles in the disk of a galaxy and is governed by a combination of escape and energy losses.

The average rate, $\dot{U}_\Sigma$, at which the SNR population produces energy in the form of relativistic particles can be expressed as

$$\dot{U}_\Sigma = \frac{U_\Sigma}{\tau_{\rm snr}}. \tag{6}$$

The relativistic particles escape from the disk at a rate of

$$\dot{U}_{\rm D} = -\frac{U_{\rm D}}{\tau_{\rm r}}. \tag{7}$$

Consider now a steady state scenario in which the energy content of the cosmic rays is independent of time over the time scale, $\tau_{\rm r}$. Then, $\dot{U}_\Sigma = -\dot{U}_{\rm D}$ and, from equations (6) and (7),

$$\frac{U_\Sigma}{\tau_{\rm snr}} = \frac{U_{\rm D}}{\tau_{\rm r}} \rightarrow \frac{U_\Sigma}{U_{\rm D}} = \frac{\tau_{\rm snr}}{\tau_{\rm r}}. \tag{8}$$

The prediction is that $U_\Sigma/U_{\rm D}$ should roughly equal $\tau_{\rm snr}/\tau_{\rm r}$, a quantity which for our galaxy is ≈ 0.003. Measurements of U_Σ and $U_{\rm D}$ can test whether SNRs can do the job.

In the above scenario, the SNRs provide the link between star formation and radio continuum emission. Since only the highest-mass stars end up as supernovae and since the highest-mass stars evolve the most rapidly there is a very tight link between the presence of star formation and the production of cosmic rays. In fact, cosmic rays can be established on time scales small compared with the duration of the star forming episode of a galaxy. Thus, to first order, any changes in the radio continuum emission of a galaxy can be correlated with changes in the star formation rate (Deeg *et al* 1977). It is for this reason that radio continuum emission has been used as a tracer of star formation in galaxies (e.g. Condon 1992). Although the above theoretical considerations are compelling, supporting empirical evidence is relatively limited.

Studies of relativistic gas in disk galaxies have taken three basic approaches. The first utilizes integrated

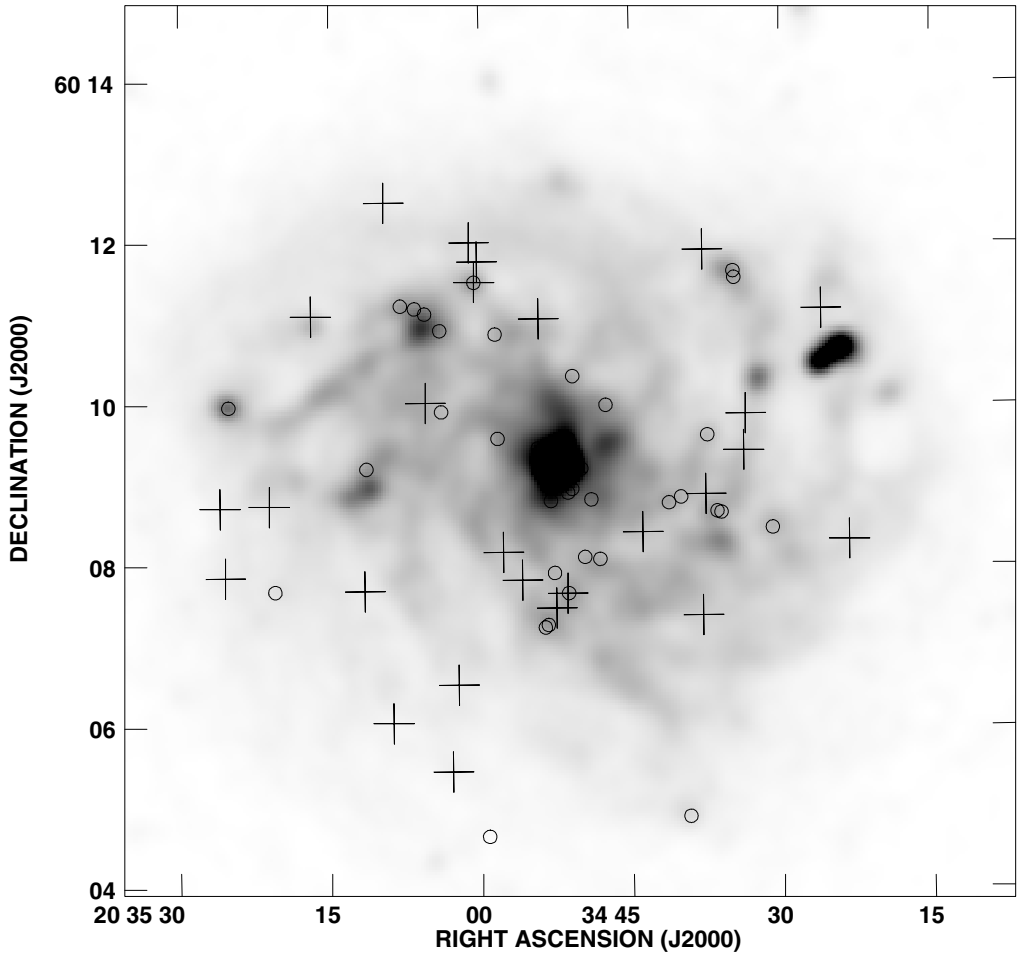

Figure 3. A 20 cm radio continuum image of NGC 6946. The resolution is roughly 60″. The open circles show the location of SNRs which are emitting detectable synchrotron radiation. These are the SNRs that are also producing cosmic ray electrons. The crosses mark the positions of an optically selected sample of SNRs which, for the most part, have no detectable radio emission and are therefore producing cosmic ray electrons in significantly lesser amounts. The correlation of the radio-emitting SNRs with the synchrotron arms of NGC 6946 suggests that these SNRs have high-mass stellar precursors and that they play a role in establishing the relativistic medium of that galaxy. The anti-correlation of the radio-quiet SNRs with the arms suggests that many of these SNRs not only are poorer sources of cosmic ray electrons but may well have an origin associated with the older, lower-mass stars. These observations are consistent with the scenario in which only those SNRs with high-mass stellar precursors play a leading role in shaping the radio continuum emission of galaxies.

properties of galaxies and is essentially a statistical study of samples of galaxies. The radio–FIR correlation (Wunderlich *et al* 1987) is a good example of this approach. This remarkably tight correlation between an indicator of star formation (top left arm in figure 1) and an indicator of cosmic ray electrons (bottom arm in figure 1) argues strongly for a physical relationship between star formation and cosmic ray production (Harwit and Pacini 1975). The scenario that has evolved from this argument is that SNRs produced by type II supernovae (resulting from recently formed high-mass stars) explosions produce relativistic particles through their interactions with the interstellar medium (Völk 1989; Condon *et al* 1991; Helou and Bicay 1993; Xu *et al* 1994).

The second approach entails analyzing and comparing light profiles in individual galaxies. Comparisons between optical light distributions at various wavelengths and high-resolution radio continuum images have been used to correlate STELLAR POPULATIONS with the relativistic gas (e.g. Duric *et al* 1996; Condon 1992). Recent results suggest that Hα and radio continuum distributions correlate the best (e.g. Duric *et al* 1996). Thus, there is an implied relationship between the very young stars (as represented by the Hα emission—top right arm in figure 1) and the relativistic gas (represented by the synchrotron emitting electrons—bottom arm in figure 1).

The two different approaches have yielded similar results in that they have established a plausible relation-

ship between star formation and the relativistic gas in disk galaxies. There is little doubt that this relationship is real. However, the physical chain of events that leads to the production of the relativistic medium can only be inferred from these studies; it cannot be directly demonstrated. In particular, the connection between SNRs and the production of relativistic particles needs to be more directly examined. This latter consideration forms the basis of a third approach, first applied to M33 (Duric *et al* 1995). In this approach, U_Σ, U_D and τ_r are determined empirically for a given galaxy, thereby enabling a direct test of the hypothesis that SNRs produce the bulk of the cosmic rays in normal galaxies.

In the prototype study of M33 the above approach was used to ascertain whether the population of SNRs resident in M33 could account for the cosmic ray electrons present in the disk of M33. It was found that the collective cosmic ray content of the SNRs is approximately 10^{52} erg whereas the entire disk contains about 10^{54} erg worth of cosmic rays. In other words, only about 1% of the cosmic rays actually reside within SNRs at any given time. This makes sense because the lifetime of a cosmic ray electron is much longer than the lifetime of an SNR. As indicated by equation (8), the ratio of energies should equal the ratio of lifetimes in a steady state configuration. Consequently, the figure of 1% is roughly what is needed to make SNRs the source of most cosmic rays in the disk of M33. The results of this study support the hypothesis that SNRs produce the bulk of the cosmic rays in galaxies, thereby supporting the chain of events that make up the bottom arm in figure 1.

An ongoing study presents an alternative approach in which the distributions of cosmic ray-producing SNRs are compared with large-scale synchrotron features in a galaxy. In figure 1, the bottom arm contains a link between the SNRs and the large-scale distribution of cosmic rays. Until now few data existed to support the view that the cosmic rays propagate from the SNRs (where they are formed) into the extended relativistic medium where they emit most of their radiation. A study of NGC 6946 by Lacey (1998) has helped fill in this gap. Her results suggest that active SNRs are spatially correlated with synchrotron arms of the galaxy NGC 6946.

Figure 3 shows a 6 cm radio continuum image of NGC 6946 (courtesy of Tom Pannuti, University of New Mexico, and Rainer Beck, Max Planck Institute for Radio Astronomy) made from combined Effelsberg 100 m single dish data and D-array VLA data. Plotted are the radio-emitting (and therefore cosmic ray producing) SNRs as circles. It is evident that the SNRs are located along ridge lines of extended radio continuum emission indicating a possible relationship between the SNR population and the large-scale distributions of cosmic ray electrons. Interestingly, those SNRs that are not radio sources (and therefore do not appear to be producing measurable quantities of cosmic rays) are not correlated with any large-scale enhancements of synchrotron emission. These may well be SNRs evolving from type supernovae whose progenitors are the older population II stars. These stars tend to be found in regions of the galaxy containing lower densities of gas compared with the population I stars. Consequently, the resulting SNRs interact with a less dense medium and produce fewer cosmic rays. These results support the standard picture in which only the SNRs with the massive stellar precursors contribute to the production of cosmic rays.

Examination of the empirical evidence in its totality points to a consistent picture in which SNRs play a central role in producing and maintaining the CR gas in normal galaxies. It therefore appears that SNRs of type II supernovae are the most likely link between star formation and the radio continuum emission of normal galaxies. In a broader context, star formation via the action of the SNRs explains not only the radio continuum emission of galaxies but also the radio–FIR correlation and the Hα correlation of galaxies.

Star of Bethlehem

The biblical Star of Bethlehem, which heralded the birth of Jesus Christ, is only mentioned in the Gospel of St Matthew 2. The astrologically significant 7 BC triple conjunction of Jupiter and Saturn in the constellation of Pisces is the most likely candidate, although a COMET/NOVA in 5 BC and a comet in 4 BC cannot be ruled out. There is also the possibility that the star was simply fictitious.

Introduction

The Jesus biblical nativity story was added, somewhat belatedly, as a prelude to only two gospels. Luke has a peculiar census/taxation system, a journey from Nazareth, an over-booked inn, a manger, a visitation of shepherds in the fields on the birth night, circumcision, purification and a journey home. Matthew has a family living in Bethlehem, a star, Herod, magi, gifts, the massacre of the innocents, a flight into Egypt and a relocation to Nazareth in the first year of the reign of Archelaus.

There is no star in Luke, and in Matthew 2 the word 'star' is used only four times. The stellar facts are as follows.

(1) As Jesus was born in the last four or so years of the reign of Herod the Great (Matthew 2:1), the star occurred sometime between 8 BC and Herod's death around Easter 4 BC. (A few, however, put Herod's death as late as January 1 BC.) This time interval considers both the Lukean census (the Roman *Monumentum Ancyranum* of Caesar Augustus dates this as 746/747 *ab urbe condita*, i.e. 8/7 BC) and the massacre of the innocents (two years old and under, Matthew 2:16) and the two years in which the Holy Family were in Egypt, sheltering from the wrath of Herod the Great. In dating the star we must ignore the hijacking (around AD 336) by early Christians of the pagan winter solstitial feast of *dies solis invicti natalis* for the celebration of the birthday of Christ. Also Dionysius Exiguus was considerably in error, in AD 525, when he based his new calendrical year numbering on the calculation that Jesus was born on 25 December, 1 BC and was about one week old on 1 January, AD 1. Jesus was six months younger than John the Baptist (Luke 1:36). Early Christian and Muslim tradition suggests that Jesus was born in the autumn and on the day after the Jewish Sabbath. It is most unlikely that the shepherds would be 'in the field, keeping watch over their flock by night' (Luke 2:8) in an Israeli December. Modern Christmas celebrations owe much to ancient pagan mid-winter Sun-worshipping customs.

(2) The magi were most probably learned Babylonian Zoroastrian priests and astrologers, and certainly not 'kings', their later beatification and royalty being mainly due to Psalms 68:29, 72:10, Isaiah 49:7 and 60:3, 60:10. They first saw the star heliacally 'in the east', '*en te anatole*', in the pre-dawn sky (Matthew 2:2).

(3) Two thousand years ago the word 'star' was a generic term for any astronomical object. Planets were wandering stars, novae were new stars, comets were hairy stars and meteors were shooting stars. All could have been the 'star' of Bethlehem.

(4) The magi talked of 'his' star (Matthew 2:2). It clearly had an astrological association with the birth of a new 'King of the Jews' (not the expected Messiah). They then traveled to Jerusalem (not Bethlehem), as ambassadors, to pay homage to this king and to present gifts. Visits by Magi were commonplace in those days. The association of stars with kings and new rulers was not unusual at the time (see Numbers 24:17).

(5) Herod and all Jerusalem had not noticed the star (Matthew 2:3) and had not witnessed its first appearance (Matthew 2:7). This indicates that the star was insignificant. Gross exaggerations as to its brightness were introduced later on by St James (*Protoevangelium*, 7, written about AD 150), Ignatius (*Epistle to the Ephesians*, XIX) and Origen (*Contra Celsum*, 1:58). Terms such as 'indescribably great', 'its light was unspeakable' and 'new' must be contrasted with the adjectivaly unadorned Matthean star.

(6) The star appeared twice. It was first seen at dawn from the magi's home town (Matthew 2:2). Its second appearance, probably in the evening southern sky, was after they had met Herod in Jerusalem, and were on the short 10 km southward journey to Bethlehem (Matthew 2:9). Their exceeding great joy on witnessing the second appearance indicates that this had been predicted, and they were pleased with the confirmation.

(7) The star 'went before them, until it came and stood over where the young child was' (Matthew 2:9). This is an astronomical stumbling block. Stars do not 'go before'. Comets have, however, been noted by contemporary historians such as Dio Cassius (*Roman History*, 54:29) and Josephus (*Jewish War*, 6:5:3) to 'stand over' individual cities. Artists also have often used comets as Stars of Bethlehem in their nativity scenes, the AD 1303 fresco in the Arena Chapel in Padua by Giotto being a famous example.

(8) The star's circumstances were uncommon. Regular astronomical events such as the stunning evening and morning appearances of Venus, and the zodiacal light, annual meteor showers, occasional fireballs and lunar occultations of Jupiter are surely so unremarkable that they would not regularly encourage magi to buy gifts and to travel long distances.

Astronomical possibilities

The facts and time frames must now be related to contemporary astronomical events. Fortunately Chinese observational astronomy was flourishing, and careful records were kept of unusual occurrences such as comets, novae, sunspots and shooting stars, for astrological purposes. Babylonian planetary astrology was also active but unfortunately only a few of the relevant clay tablets have been found. Ho (1962) recorded contemporary Far Eastern diary records. His object number 61 was Comet Halley. This was seen in 12 BC, as a *po-hsing* (a comet without a tail), but was too early.

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS21 6BE, UK

For 70 days between 9 March and 6 April 5 BC a *sui-hsing* (a comet with a tail) was recorded in Capricornus near the asterism Chhien-niu (RA 20.25 h, dec 15°). As no details are given as to the motion of this object, Clark *et al* (1977) take it to be a nova. The long duration is taken to indicate that it was bright.

A comet (*po-hsing*) was seen in April 4 BC near Ho-Ku in Aquila (RA 19.6 h, dec +8°). Duration details are not given so this comet was probably faint and short-lived.

Ho's object number 65, a comet seen in December AD 13, is far too late.

The Star of Bethlehem might have been a planetary conjunction. Here the Earth-based observer sees two or more PLANETS nearly along the same line of sight, this producing an impressive grouping on the celestial sphere. There was a significant triple conjunction of Jupiter and Saturn in 7 BC in Pisces. These planets have orbital periods of 11.9 and 29.5 yr respectively and thus pass each other in the sky every 19.9 yr. Every 120 yr or so, the Sun is also close to the Earth–Jupiter–Saturn line giving three conjunctions in about six months. Every 796.4 yr these triple conjunctions take place in Pisces, the last being in April 1573. In February 6 BC Mars joined Jupiter and Saturn forming a 'massing' only 8° across.

One advantage of a planetary conjunction 'star' is that the astronomical and astrologically uninterested would most likely not know it was happening, and, with the exception of point (7), it fits the facts. A planetary conjunction would have a clear message to astrological magi. It would tell them where to go, when to go and what to expect when they got there. Kennedy and Pingree (1971) noted how an 8th century AD astrological world history by Masha'allah, based on earlier Babylonian and Iranian ideas, stressed the role of Jupiter–Saturn 'great' conjunctions as heralds of important religious and political events. The Noachian deluge and the births of Jesus and Mohammed were mentioned particularly. In AD 1497 Don Isaac Abrabnel stressed that the constellation Pisces was specifically associated with Israel in Magian astrology. Saturn was regarded as the old ruler (and father), with Jupiter as the new king, and son. Both interpretations are unfortunately *post facto*. Predictions of the 7 BC triple conjunction have also been found on Babylonian clay tablets (see Sachs and Walker 1984).

A Jupiter–Saturn–Mars massing was observed in 1604 by Johannes Kepler. The contemporary appearance of the supernova of 1604 convinced Kepler that the latter was the Star of Bethlehem.

Other conjunctions have been suggested. Sinott (1968) and Mosley (1987) concentrated on the rather late June 2 BC close conjunction of Jupiter and Venus near Regulus in Leo. Much is made of the Judea–Lion association and of the possibility that Herod might have lived until just after the total lunar eclipse of 10 January 1 BC as opposed to the partial lunar eclipse of 13 March 4 BC.

Molnar (1999) reinterprets the astrological evidence. He is convinced that the constellation associated with Israel was not Pisces but the adjacent sign Aries. This is not only favoured by the Egyptian–Greek astronomer–astrologer Ptolemy, in his *Tetrabiblos*, but is also supported by Syrian coinage which shows a leaping Ram peering over its shoulders at a star. A diligent search is then made of the astronomical records for events that take place in Aries. Molnar also assumed that the Magi are Hellenistic astrologers, and comparisons are made with the natal horoscopes of other 'kings' such as the Emperor Hadrian and Antiochus I of Commagene. Jupiter and the Moon have important roles to play in these regal horoscopes, and there were two lunar occultations of Jupiter, in Aries, in 6 BC, one on 20 March, and the other on 17 April. As the first was 'weakened' by the nearness of the Sun in the sky Molnar chooses the second and suggests that Jesus was born on 17 April in 6 BC.

Unfortunately this thesis has certain problems. Both events were invisible. The 20 March occultation of Jupiter by the Moon occurred just before sunrise, and the 17 April occultation occurred at local noon. So the fact that Matthew stresses that the 'star' was 'seen' twice is ignored. Molnar surmises that astrologers only needed to calculate that something happened for it to be significant. However, even though Babylonian astronomers could easily predict planetary conjunctions and massings, the fact that the Moon is only 0.5° across, and lunar theory is extremely complicated, means that predicting occultations was way beyond them. We have to wait for the 17th century and a genius like Edmond Halley before lunar occultations could be predicted with any accuracy. Also, lunar occultations of Jupiter are most probably just too common to be the Star of Bethlehem. Jupiter is in Aries for 1 yr in every 12, and the Moon, in that year, moves through Aires 12 times.

Let us now consider the nova/comet in Capricorn, seen during March and April 5 BC, and the tail-less comet, or nova, seen in Aquila in April 4 BC. The former is favoured by Humphreys (1993) and by Clark *et al* (1997). Comets (which in those times were regarded as meteorological phenomena) have the advantage of 'standing over' specific places for short times. However, astrologically, comets are regarded as rather broad-brush indicators of doom, diseases, disaster and the death of kings. Needless to say, the death of one king could be good news for his successor. The snag with comets and novae is that they are completely unexpected. The astrology of comets is associated with the constellation that they appear in and the form and direction of their tails. Neither Capricornus nor Aquila has anything to do with Judea. Novae and comets brighten and then decay. They are not seen twice, as the Star of Bethlehem was. Comets are usually only seen after they have passed the Sun. It is an unusual comet that is seen both on its way in to the Sun and again on its way out. In this unusual case, we have had to wait for Isaac Newton, in the 1680s, to show that the same object was being seen on both occasions.

So the 'exceedingly great joy' of the magi, a joy that is often taken to indicate that one of their celestial

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS21 6BE, UK

predictions had come true, and the same object had been seen twice, does not apply to comets or novae. Also, the 5 BC comet, that is seen for 70 days, will be bright at maximum, and it is then difficult to explain why Herod had not seen it and was taken by surprise by the Magi's visit.

Let us return to the triple conjunction of 7 BC. Both Jupiter and Saturn were in opposition in Pisces and were moving around their retrograde loops. During late 8 BC and early 7 BC the planets approached each other at about 3.5° per month. On 27 May 7 BC they were only 1° apart (twice the lunar diameter). They then separated slightly, and by 27 July were 2.9° apart. Coming together again they were 1° apart on 6 October, 1.2° apart on 1 November and 1.05° apart on 1 December. During 6 BC they moved away from each other, as quickly as they had come together in early 7 BC. A 1° separation is not startling. This sight could easily be ignored by the astrologically uninterested. The close conjunctions in May and October–November provide an ideal 'two stars'. The six months between these two events also gives ample time for the Magi's preparation and travel. Proponents of this theory (for example Hughes 1976, 1979) regard Jupiter as the Star of Bethlehem. The date of the birth of Jesus is still uncertain but the astrologically minded Magi would have possibly associated it with the acronychal rising of the two planets, i.e. Tuesday 15 September 7 BC. The magi would have predicted this. There was no rush. They did not have to pay homage to the new King of the Jews on his actual day of birth; any time when he was a young child would do. Unfortunately, like most astronomical interpretations, the 'going before' and 'standing over' is still a problem.

Conclusion

The astrological interpretation of the Star of Bethlehem has one great snag. It gives a degree of credence and verisimilitude to a subject that is a quagmire of subjective, unscientific partiality. This interpretation has the star as a tangible physical phenomenon.

There are two other possibilities. One abrogates the scientific interpreter of all responsibility and regards the whole phenomena as miraculous. The passage of one age and the dawn of the next is thus heralded by a miraculous occurrence, and as such the star is inexplicable.

A more appealing proposal is that the star is an example of *midrash*. Thus it is nothing more than a fictitious invention giving fulfilment to the Old Testament prophecy of Balaam in Numbers 24:17 ('there shall come a star out of Jacob'). The Star of Bethlehem would then join a host of other fascinating historic stars and comets that were thought to foretell the birth and death of heroes, kings and emperors. Matthew would have used it to add credence to the messianic nature of Jesus and to encourage more of his Jewish audience to convert to Christianity.

However, if it was an invention, why did Matthew omit one of his favourite phrases, 'that it should be fulfilled', and why did he invent such an ordinary star, or one that had such similarities to an actual celestial occurrence? To me the Gospel of St Matthew rings true. Its message is unembellished. I believe that the Star of Bethlehem actually existed, and that astronomical historians will enjoy searching for it for many years to come.

Starburst Galaxies

A starburst galaxy is one undergoing a brief episode of intense STAR FORMATION, usually in its central region. The massive stars in the burst generate most of the total luminosity of the entire galaxy. Starburst galaxies are fascinating objects in their own right and are the sites where roughly 25% of all the massive stars in the local universe are being formed. They offer unique laboratories for the study of the formation and evolution of massive stars, the effects of massive stars on the interstellar medium and the physical processes that were important in building galaxies and chemically enriching the INTERGALACTIC MEDIUM.

What is a starburst?

Overview

There is no rigorous definition of a starburst galaxy, but several different criteria are often used. These are clear conceptually, but each is subject to uncertainties in its application.

Starbursts are usually located in the centers of galaxies, and have typical radii of 100–1000 pc (1–10% of the size of their 'host' galaxy). Despite their small size, they are converting gas into massive stars at a rate that exceeds that found throughout the rest of their host galaxy. The starburst is 'fueled' by a copious supply of interstellar gas (primarily in the form of molecular hydrogen) that has been accumulated in the center of the galaxy. The available gas supply is sufficient to sustain the current rate of star formation for only of order 10^8 yr ($\sim$1% of the age of the universe). The dust grains associated with the molecular gas usually absorb most of the radiation produced by the burst's stars. This can make it difficult to determine many of the basic properties of starbursts.

Star-formation rates

We do not directly measure the star-formation rate in a starburst but must infer it from measurements of the starburst's luminous output. Two techniques are routinely used.

The first is to use the bolometric luminosity of the starburst ($L_{\rm bol}$), which is the luminosity integrated over the entire electromagnetic spectrum. $L_{\rm bol}$ for a starburst is dominated by the emission from hot, massive, short-lived stars. These have masses greater than about 8 times the mass of the Sun ($M > 8M_\odot$) with lifetimes of less than about 40 million years. The bulk of the radiation from these stars is emitted in the ultraviolet part of the spectrum. Dust grains in interstellar medium of the starburst absorb this radiation, are heated, and cool by emitting far-infrared radiation. Thus, a good approximation of $L_{\rm bol}$ is given by the sum of the starburst's ultraviolet and infrared luminosities.

The second technique uses measurements of the amount of ionizing radiation produced by the starburst (often denoted by Q, the total number of photons produced per second that are capable of ionizing atomic hydrogen). The production of these ionizing photons is dominated by the most massive, shortest-lived stars ($M > 25M_\odot$ and lifetimes less than 7 million years). Measurements of Q are based on measurements of the rate at which H ions and electrons recombine, which in turn is measured by the luminosity of the so-called recombination emission lines of hydrogen (after the luminosity is corrected for absorption due to dust inside the starburst).

Given a measurement of $L_{\rm bol}$ or Q, we can estimate the mass of the population of massive stars required to produce this quantity. If we divide this mass by the lifetime of the appropriately massive stars we obtain an estimate of the mean formation rate of the massive stars. This technique tells us almost nothing about the rate at which low-mass stars (like our Sun) are being formed, since these stars contribute only a negligible amount to $L_{\rm bol}$ or Q. Indeed, it is entirely possible that starbursts form only massive stars (unlike the mode of star formation in normal galaxies like our own). If we assume that starbursts form a normal complement of low-mass stars, the implied star-formation rates usually range from $1M_\odot$ to $100M_\odot$ yr^{-1}.

The burst intensity

A useful way to define a starburst is to consider the burst intensity—the rate of star formation per unit area ($\Sigma_{\rm SFR}$—typically given in units of $M_\odot$ per year per kiloparsec^2). In normal star-forming galaxies like our own Milky Way, the star-formation rate is a few $M_\odot$ per year throughout a galactic disk with a radius of about 10 kpc (e.g. $\Sigma_{\rm SFR}$ has a typical value of $10^{-2}M_\odot$ yr^{-1} kpc^{-2}). In a typical starburst galaxy, the star-formation rate would be $10M_\odot$ yr^{-1} in a region with a radius of 0.5 kpc. The implied $\Sigma_{\rm SFR}$ is then $10M_\odot$ yr^{-1} kpc^{-2}, or 10^3 times greater than in a normal galaxy.

It is important to emphasize that there is no particular 'magic' value for $\Sigma_{\rm SFR}$ that separates normal and starburst galaxies. A continuum of values is observed, spanning at least 6 orders of magnitude from the most quiescent star-forming normal galaxies to the most intense starbursts.

Although calculating a global value for $\Sigma_{\rm SFR}$ is a useful way to quantify a starburst, star formation is not uniformly distributed throughout the bursting region. Instead, the star formation occurs both in compact (few parsec scale) star clusters and in a more smoothly distributed mode. The most massive CLUSTERS (the 'super star clusters') have estimated masses of (10^5–10^6) $M_\odot$ and may be close analogs to young GLOBULAR CLUSTERS.

The burst duration

A starburst is by definition a transient event. The duration of a starburst (Δt) must be much smaller than the age of the galaxy in which it occurs ($\Delta t \ll 10^{10}$ yr). Another way of stating this requirement is that the present rate of star formation must greatly exceed the past rate averaged over the age of the galaxy. Unfortunately, it is difficult to accurately determine how long starbursts last.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Perhaps the most commonly used technique to estimate Δt is to calculate the gas-depletion time: the mass of interstellar gas in the starburst divided by the present rate of star formation. This is then a rough estimate of how much longer the starburst can be sustained before running out of gas. Gas-depletion times in starbursts are usually of order 10^8 yr, but they are highly uncertain for many reasons. For one thing, the mass of molecular gas is difficult to determine to better than a factor of a few since the determination relies on indirect arguments and observations of a trace molecule (usually CO). The estimated molecular gas masses range from $10^8 M_\odot$ to $10^{10} M_\odot$, increasing as a function of the luminosity of the starburst. In addition, the star-formation rate itself is quite uncertain, primarily because we do not know the rate at which low-mass stars are being formed (see above).

More sophisticated estimates of the duration of starbursts utilize measurements of Q, $L_{\rm bol}$ and the starburst mass plus detailed information on the stellar population (for example the relative numbers of massive main sequence and post-main-sequence stars such as red supergiants and Wolf–Rayet stars). These measurements are then compared with models for the evolution of a population of massive stars (see STELLAR EVOLUTION). Resulting estimates for burst duration range from a few million years for the smallest and least powerful starbursts (which occur in dwarf galaxies), up to 10^7 or 10^8 yr for powerful starbursts.

More generally, the minimum possible duration of a starburst is set by considerations of causality: the duration of star formation cannot be significantly less than the time for gas on one side of the starburst to 'communicate' with gas on the other side. Such 'signals' will travel at speed of sound in the gas or the velocity induced by the gravitational field in the starburst. These velocities will be of order 10^2 km s^{-1}, so $\Delta t > 10^7$ yr for a starburst with a diameter of 1 kpc. The most powerful and intense starbursts seem to turning gas into stars as fast as allowed by causality.

How do we find starburst galaxies?

The massive stars that power starbursts are mostly very hot ($T \sim 20\,000$–$50\,000$ K) and emit most of their radiation in the ultraviolet between 912 Å and roughly 2000 Å. Thus, one technique for finding starbursts is to search for galaxies that are unusually bright in the ultraviolet. The spectral region below about 3200 Å is inaccessible from the surface of the Earth, so most ultraviolet surveys for starbursts in the local universe have been conducted in the near-ultraviolet region just longward of the atmospheric cut-off. This will change in the near future as space-based ultraviolet imaging surveys are conducted at shorter wavelengths.

Starbursts are rich in interstellar gas and dust (the raw material for star formation). The primary radiative output from the massive stars (ultraviolet radiation) is absorbed by this interstellar material which then re-radiates the energy in other forms. The gas absorbs nearly all the stellar photons with energies sufficient to photoionize neutral hydrogen ($E > 13.6$ eV, or $\lambda < 912$ Å). The subsequent recombination of hydrogen or helium ions and resulting radiative cascade produce H and He recombination emission lines. The free thermal electrons in the gas can also collisionally excite ions, whose radiative decay produces emission lines. Many of the strongest lines of both types are in the visible part of the spectrum, and together constitute a few per cent of the bolometric luminosity of the starburst. Thus, another way to find starbursts is to search for galaxies with unusually bright emission lines.

The dust grains in the starburst are effective at absorbing ultraviolet photons of all wavelengths. The grains are heated by this radiation and cool by emitting radiation. The equilibrium temperatures that result from balancing heating and cooling rates are usually in the range 10–100 K, and the emitted radiation therefore lies in the mid- and far-infared spectral region ($\lambda \sim 30$–300 μm). The survey by the INFRARED ASTRONOMY SATELLITE (IRAS) in the 1980s (which surveyed nearly the entire sky in the mid and far infrared) has produced the most extensive and best-studied sample of starbursts.

These three types of surveys select samples of starbursts that overlap one another but nevertheless have important systematic differences. The most direct difference is that dusty starbursts are preferentially detected in the far-infared surveys, while the less dusty starbursts are preferentially found by the ultraviolet and emission-line surveys. Dust grains are made of elements heavier than H or He ('metals'). Thus, the dust-content of starbursts correlates well with chemical composition: typically only a few per cent of ultraviolet radiation escapes 'metal-rich' starbursts (having chemical composition like the Sun) while the majority of the ultraviolet light escapes the most 'metal-poor' starbursts. Metal-poor starbursts tend to be less powerful and to occur in smaller and less massive galaxies (as a result in part of the well-known mass–metallicity relation for galaxies).

What causes a starburst?

From a purely empirical point of view, the causes of starbursts become increasingly clear for starbursts of greater and greater luminosity. The most luminous starbursts in the local universe are the so-called 'ultra-luminous infrared galaxies', which have bolometric luminosities of roughly $10^{12} L_\odot$ (nearly all of which is emitted in the mid- and far-infrared). The power source is deeply buried inside a dense, dusty region of molecular gas only a few hundred parsecs in size and may consist of a combination of a starburst and a dust-enshrouded QUASAR. The mass of molecular gas ($\sim 10^{10} M_\odot$) is comparable with the entire mass of the interstellar medium in a big SPIRAL GALAXY.

These ultraluminous galaxies almost invariably have highly disturbed morphologies that are strongly suggestive of the ongoing or recently completed merger of two large DISK GALAXIES. Specific morphological structures indicative of mergers include long narrow 'tidal tails'

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of stars and gas (the remnants of the outer disks of the merging galaxies) and double nuclei. For less powerful starbursts the evidence suggests that more mild gravitational interactions between galaxies are an important triggering mechanism (e.g. the close passage of two galaxies, without their subsequent merger).

During the close passage of two galaxies, tidal stresses act to strongly perturb the orbits of the stars and gas in the galaxy disk. The dissipation of kinetic energy as gas collides with gas allows the gas to become sufficiently displaced from the stars that gravitational torques act between the stars and gas to transfer significant amounts of angular momentum from the gas to the stars. The gas can thereby flow into the center of the galaxy, where it can fuel a starburst. If the passage of the two galaxies is slow and interpenetrating enough, dynamical friction can transfer enough kinetic energy from the stars to the galaxy dark-matter halos to allow the two galaxies to merge into a single galaxy. Such mergers or strong interactions should take a few times the galaxy rotation period (about 10^9 yr), with the intense starburst phase being significantly shorter (see GALAXIES: INTERACTIONS AND MERGERS). These timescales are loosely consistent with independent estimates of starburst lifetimes discussed above.

However, many starbursts are not found in obviously interacting systems. In such cases, a stellar bar is often present in the inner disk of the starburst galaxy. A bar can act to rob gas of its angular momentum, and transfer gas into the center of the galaxy where it can fuel a starburst. The mechanism for triggering starbursts is most uncertain in the lowest-power starbursts, which occur in DWARF GALAXIES. In some cases it appears that the dwarf may have recently collided with an extragalactic gas cloud, but in most cases there is no clear evidence for any type of interaction or stellar bar.

Starbursts from a cosmological perspective

Starbursts in context

How important are starbursts? The far-infrared IRAS survey produced the best-studied sample and shows that starbursts provide about 10% of the bolometric luminosity of the entire local universe. Using the luminosities of the H recombination lines to estimate the star-formation rate (as described above), it appears that roughly 25% of all the massive stars in the local universe are formed in starbursts, while the rest are formed in the many-kpc-sized disks of normal galaxies like our own. While the measurements are difficult, and their interpretation is uncertain, a similar situation seems to hold out to a REDSHIFT of about 1 (over half the way back to the big bang).

At still higher redshifts, it becomes almost impossible to measure the amount of star formation in the large-scale disks of normal galaxies. The great distances and redshift-dimming of the light mean that only intense and luminous regions of star formation can be readily detected. The detected objects appear rather similar to local starbursts (see below), and by themselves can plausibly account for much of the early star formation in the universe. Thus, starbursts are indeed highly significant components of the universe, past and present.

Starbursts as analogs to high-redshift galaxies

As described above, starbursts in the local universe are often selected by either their ultraviolet or their far-infrared continuum emission or by visible-band emission lines. At high redshifts ($z > 2$) the rest-frame ultraviolet, visible, and far-infrared emission from a star-forming galaxy will be observed in the visible near-infrared, and submillimeter spectral regions respectively (see GALAXIES AT HIGH REDSHIFT). With the Hubble Space Telescope and modern 10 m class ground-based telescopes operating in the visible and near infrared, and rapid advances in submillimeter astronomy, it is now possible to detect and study such high-redshift galaxies.

The ultraviolet-selected galaxies at high redshift strongly resemble similarly selected local starbursts: they have similar values for Σ_{SFR}, similar ultraviolet colors (suggesting a similar amount of reddening due to dust absorption), and their ultraviolet and visible spectra show that they have similar stellar populations and gas dynamics. One important difference is that the regions of star formation in the high-redshift galaxies are typically larger and more luminous than in ultraviolet-selected local starbursts. Depending on the uncertain corrections for dust extinction, the ultraviolet luminosities of the most powerful high-redshift galaxies imply star-formation rates that can reach several hundred $M_\odot$ per year over a region a few kpc in size. To date, less is known about the nature of the submillimeter-selected galaxies at high redshift. The available information suggests that these objects resemble the local ultraluminous galaxies described above.

It appears that the physical processes that we can study in considerable detail in local starbursts are directly applicable to high-redshift galaxies.

Galactic 'superwinds'

One of the most important processes that has been observed in both local starbursts and star-forming galaxies at high redshift is the bulk outflow of warm and hot gas at velocities close to or even exceeding the escape velocity from the galactic gravitational potential well (a phenomenon sometimes called a 'superwind'). Superwinds are driven by the collective effect of the kinetic energy that is deposited in the interstellar medium by stellar winds and supernova explosions. It is believed that this kinetic energy is converted (via shocks) into thermal energy inside the starburst. The resulting hot gas has a pressure much greater than its surroundings, and so it will expand most rapidly along the direction of the steepest pressure gradient in the interstellar medium (e.g. along the minor axis of the galaxy's gas disk). This leads to a poorly collimated bipolar outflow.

In local starbursts, there are a variety of probes of superwind physics. The hot outflowing gas produces thermal x-ray emission, and spectroscopy of this gas implies temperatures of 3–10 million K. This hot gas can

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

be traced out to radii of 10–30 kpc from the starburst (well out into the halo of the galaxy). The inferred outflow speeds for the hot gas are of order 10^3 km s^{-1}. Warm gas mixed into the outflow ($T \sim 10^4$ K) produces recombination and collisionally excited emission lines in the visible, and the measured Doppler shifts imply outflow speeds ranging from 10^2 to 10^3 km s^{-1}. Spectroscopy in the ultraviolet probes gas seen in absorption against the starburst. The measured blueshifts provide direct evidence for the outflow of warm and cool gas at velocities of 10^2–10^3 km s^{-1}. The ultraviolet signature of superwinds is by far the easiest one to observe in high-redshift galaxies, and it shows that outflows were common in the most actively star-forming galaxies in the early universe.

The data on both local and high-redshift superwinds establish that the outflowing material is enriched in the heavy elements (metals) that are the nucleosynthetic byproduct of massive stars (see NUCLEOSYNTHESIS). Where do these metals go? In CLUSTERS OF GALAXIES today, the amount of metals in the intergalactic medium exceeds that contained in all the stars in all the cluster's galaxies. Observations of the intergalactic medium at high redshift show that it contains at least trace amounts of metals. Thus, superwinds operating over the history of the universe are probably responsible for 'polluting' the intergalactic medium with metals.

Steady-State Theory

A theory which postulates that the large-scale appearance of the universe does not change with time. The theory, devised in 1948 by Hermann Bondi, Thomas Gold and Fred Hoyle, satisfies the so-called 'perfect cosmological principle' that the universe is the same everywhere at all times. This theory avoided the necessity for a 'Big Bang' origin to the universe, but required the continuous creation of matter in order to maintain a constant uniform density in the universe at all times (new galaxies formed as the older ones moved apart, thereby maintaining the same average number of galaxies in each large volume of space). The discovery, in 1965, of the cosmic microwave background radiation, which could not naturally be explained by the steady-state theory, led to the rejection of the theory.

Stellar N-body Systems: Dissipation

The motions of the stars are usually assumed to be perfectly frictionless, whereas in everyday life objects slow down by the action of friction, and heat is generated. Large collections of stars do, however, behave in ways which are reminiscent of this more familiar behavior.

Stellar N-body systems (e.g. STAR CLUSTERS, GALAXIES, MULTIPLE STARS) can be treated to a high degree of approximation as collections of point masses[1], moving according to Newton's Laws[2] of motion and gravitation. In this approximation they conserve energy[3]: if the stars fall together (figure 1) then they lose potential energy, but gain an equal amount of kinetic energy. In familiar situations such behavior is rare: a falling tennis ball also converts potential energy to kinetic energy as it descends, but it loses energy at each bounce, and by friction with the air. Eventually it loses all its energy and comes to rest. 'Dissipation' is a term applied to any process by which a system (like the bouncing ball) loses energy. By contrast, stellar N-body systems are *dissipationless* to a very good approximation. The stars do not come to rest.

Though the energy of a bouncing ball is dissipated it does not disappear. It is lost in the sound energy produced when the ball hits the ground, and in the thermal energy produced by distortions in its shape as it bounces. Thus the energy is simply converted from one form to another.

In much the same way the energy of a stellar N-body system can decrease if stars escape. This is analogous to the sound waves generated by a bouncing ball (though sound waves, unlike escaping stars, carry no mass).

Similarly the energy of a stellar N-body system can be transformed in a manner analogous to the generation of heat. To understand this, imagine a system in which all stars are initially at rest. They start to fall towards each other, like a dropped ball falling to the ground (figure 1). They pass beyond the point at which they are all close together, and then the system expands again. By a process referred to as *violent relaxation* (see below) the subsequent recollapses and re-expansions become weaker, like the weakening bounces of a ball. The system appears

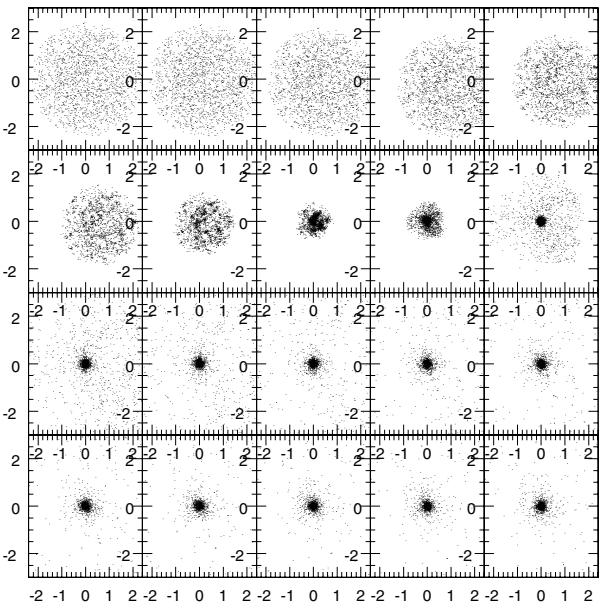

Figure 1. Collapse of a stellar N-body system. Initially the particles are at rest and distributed uniformly inside a sphere. The frames are read from left to right within each row, and the rows are read from top to bottom.

to settle down, but close examination would show that the individual stars are now moving in rather random directions within it: it is in *dynamic equilibrium*. What has happened is that the kinetic energy of the original contraction, which is an ordered motion like that of a falling ball, has been converted into kinetic energy of random motions, like the thermal motion of atoms and molecules. Indeed the collapse in the first few frames of figure 1 is called *cold collapse*, and the final configuration is referred to as a *hot system*.

On a much longer time scale the further evolution of a hot stellar system is determined by the way it cools down. Like ordinary objects, stellar systems become denser as they lose heat, but paradoxically their temperature *increases*! This intensifies the flow of heat, and leads to an accelerating collapse of the central part of the system. This process is known as 'core collapse'. It is eventually halted when the stars are so crowded together that triplets of stars can interact energetically enough. Then the system reaches a sort of equilibrium, but is gradually losing stars. Eventually the remnants of the system are indistinguishable from their surroundings, and the life of the system has come to an end.

Violent relaxation

First we consider in detail why the oscillations in figure 1 appear to damp out. Initially the stars are randomly distributed inside a sphere, and, by Newton's Theorem[4],

[1] *Point mass*: in classical dynamics, a point in space endowed with a mass, and moving according to Newtonian dynamics. It is a good approximation for a body if its dimensions are much smaller than the distances between the bodies, as in a star cluster.

[2] *Newton's Laws*: the principal *Law of Motion* (the second of the three) states that $f = ma$, where f is the force on a body of mass m, and a is the resulting acceleration; the *Law of Gravitation* states that each body exerts on every other body an attractive force of magnitude GMm/r^2 along the line between them, where m, M are their masses, r is their distance apart, and G is the universal constant of gravitation.

[3] *Energy*: in classical gravitation, the sum of the *potential* and *kinetic* energies. The potential energy depends only on the position and mass of the bodies (if treated as point masses), and increases as their separation increases. In gravitating systems it is usually taken to be negative, increasing to zero as the bodies move infinitely far apart. The kinetic energy depends only on their speeds and masses, and increases with increasing speed.

[4] *Newton's Theorem*: a uniform sphere of matter attracts an outside particle as if the entire mass of the sphere were concentrated at its centre.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

on average the gravitational force a star experiences is directed towards the center of the sphere. In this approximation, all stars would arrive at the center at the same time. If the initial density of the stars (i.e. their mass per unit volume) is ρ, then this time is the 'free-fall' time

$$t_{\rm ff} = \sqrt{\frac{3\pi}{32G\rho}}.$$

In fact each star is particularly affected by its neighbors and by fluctuations in the distribution of stars around it. Consequently, some stars arrive late at the center, some early, and most stars pass on one side or other of the exact center. The result is that the system reaches a *finite* maximum density at the end of the collapse, from which the stars re-emerge in a phase of expansion.

The fact that stars do not quite arrive at the center at the same time is partly an effect of *phase mixing*. Roughly speaking, we say that motions are 'in phase' if they all arrive at one configuration at one time, and 'phase mixed' if they arrive at various times.

Another factor which helps to explain the gradual emergence of random motions is an *instability* of cold systems like the initial conditions in figure 1. This results in an increasing clumpiness in the distribution of the stars, as can be seen in the seventh and eighth frames in figure 1. The instability is analogous to the Jeans instability of cold self-gravitating gases. The effect of these clumps is that large groups of neighbors can influence each other *en masse* (or 'collectively').

Such processes continue to affect the motions of stars during the first re-expansion and subsequent collapses, though these are difficult to see in figure 1. Eventually the oscillations die away, and all that is left are the random motions of the stars. This decay of ordered motions is a rather common feature of stellar systems, and the various processes which give rise to it are referred to as 'collisionless relaxation' or 'violent relaxation'.

These words require some explanation. A process is called 'collisionless' if it is dominated by collective interactions, in contrast with 'two-body' relaxation, described below. The word 'relaxation' itself is applied to many processes which lead to equilibrium. In this case it is a 'dynamic' equilibrium, in which the stars are all in motion, but the overall distribution of density is nearly static. The word 'violent' is commonly used because it captures the time dependence of the overall distribution of matter (cf figure 1). The time scale on which violent relaxation acts is given in order of magnitude by the free-fall time. The hot system to which it gives rise is approximately in virial equilibrium[5], and so the process is often also referred to as 'virialization'.

[5] *Virial equilibrium*: the potential energy, W, and the kinetic energy, T, of a system of gravitating bodies in dynamic equilibrium are related approximately by $2T + W = 0$.

Escape

Consider a stellar system similar to that in the last frame of figure 1. The density of stars is nearly stationary and can be described approximately by the stellar density ρ, which will depend on position but not on time. By Poisson's equation, i.e.

$$\nabla^2\phi = 4\pi G\rho$$

where G is the universal constant of gravitation, the mass generates a potential ϕ, in which the stars move. In this context the energy of a star of mass m is

$$E = \frac{mv^2}{2} + m\phi$$

where v is its speed. (The two terms are the kinetic and potential energies, respectively.) Since E is constant and ϕ may be defined so that it vanishes at large distances, a star may escape 'to infinity' provided that $E > 0$, i.e. $v > \sqrt{-2\phi}$. The quantity on the right is the *escape speed*.

In the stellar N-body systems in nature, escape is complicated by the gravitational attraction of stars outside the stellar system. At some finite distance from a stellar system their gravity begins to dominate the motion of a receding star. Therefore escape is possible at slightly lower energies, and in consequence is easier. In addition, the force exerted by outside matter may vary with time, as when a star cluster passes by the dense central part of its parent galaxy. Then the energy of the star is no longer constant, and may change sufficiently to lead to escape.

Two-body relaxation

If all stars in a system have energy $E < 0$, it does not follow that escape will never happen (even if we ignore stars outside the system). Though we stated that E is constant, this was true only because we chose to describe the stellar system in terms of a steady density ρ. In reality, when two stars come close together this approximation is not valid, and at such times the energy of the two participants will change. Even if both stars initially had insufficient energy to escape, one or other of them may gain enough energy in the encounter to escape subsequently.

This process, by which the energy of a star may change because of encounters, is called *two-body relaxation* or *collisional relaxation*, and its role is not restricted to escape (see the section on 'Collapse' below). Though the description 'two-body' is self-explanatory, the other terms require some explanation. As before, 'relaxation' refers to a process which leads to a steady state (cf 'violent relaxation', above). Here the steady state refers to the particular ('Maxwellian') distribution of velocities $\boldsymbol{v}$ to which two-body encounters would give rise in the absence of escape, i.e. a distribution function

$$f(\boldsymbol{v}) = \frac{n}{(2\pi\sigma^2)^{3/2}} \exp\left(-\frac{v^2}{2\sigma^2}\right)$$

where n is the number of stars per unit volume, and σ is the root mean square value of one velocity component. This

corresponds to a state of thermal equilibrium (a steady state in which all parts of a body or system have the same temperature) in gases, where similar effects occur. In the classical theory of gases, however, the relaxation is caused by actual collisions between the atoms or molecules. Though the term 'collisional' is also used in the theory of stellar systems, it is misleading, as the interaction of a pair of stars is purely gravitational. Real collisions do take place in extreme circumstances (see below), but have no role in relaxation.

The time scale on which relaxation acts is called the *relaxation time*, and varies according to the density ρ, and other factors. For a stellar system of the type we are considering, a convenient measure is the so-called *half-mass relaxation time*

$$t_{\rm rh} = 0.138 \frac{N^{1/2} r_{\rm h}^{3/2}}{m^{1/2} G^{1/2} \ln \Lambda}$$

where N is the number of stars, m is the mass of a single star, Λ is roughly equal to N ($t_{\rm rh}$ is rather insensitive to the exact value) and the *half-mass radius* $r_{\rm h}$ is the radius of an imaginary sphere centered at the center of the cluster, and enclosing half of its total mass. Stars escape from a stellar system on a roughly comparable time scale. Another process acting on this time scale is called *dynamical friction*, because rapidly moving stars tend to lose kinetic energy to the stars which they encounter.

This formula applies to the idealized case of a stellar system in which all stars have the same mass. In more realistic cases, the effects of relaxation depend on the stellar mass. In particular, massive stars suffer greater dynamical friction than stars of low mass. One result of this is that the rate of escape of stars decreases with increasing mass. Another result is *mass segregation* (see below).

Collapse

As we have seen, a star may escape from a stellar system following a close encounter with another star. This dynamical process is dissipationless: the total energy of all stars is constant. The escaping star removes some energy, however, and so the energy of the remaining stars decreases. In this section we consider how the stellar system evolves as it loses mass and its energy decreases.

Because the system is nearly in virial equilibrium its kinetic energy, T, is related to its total energy, E, by

$$T = -E.$$

As E decreases, following escape, T necessarily increases. As this kinetic energy is also shared among fewer stars, it follows that the velocities of the stars increase on average. It is not difficult to see why this happens. Consider a planet in circular orbit about the Sun, and suppose we decrease its energy by slowing it down slightly. It now falls towards the Sun somewhat, but in doing so it picks up speed. In fact it now moves, on average, faster than it did before we slowed it down. For the same reason, though an Earth satellite suffers from friction if it dips into the top of the Earth's atmosphere, it actually speeds up as it descends.

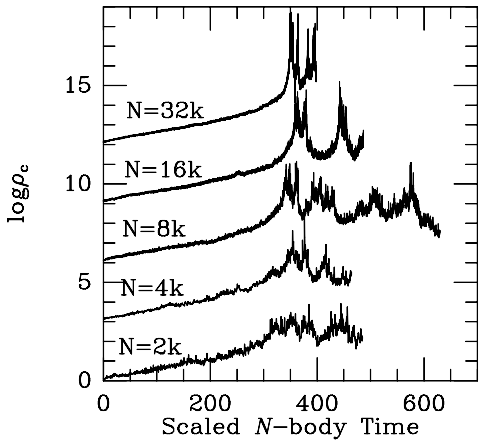

Figure 2. Core collapse in several computer simulations. The central density is plotted against time, scaled in proportion to $t_{\rm rh}$. The first 'spike' marks the end of core collapse and the start of a phase of gravothermal oscillations. (After Makino J 1996 *Astrophys. J.* **471** 796–803. Reproduced by permission of the American Astronomical Society.)

This remarkable property of gravitating systems is sometimes described by saying that they have 'negative specific heat'. The 'specific heat' of a substance describes the effect on its temperature of the addition of some energy, and for familiar substances like water or air it is positive. This increase in temperature corresponds to an increase in the speeds at which the atoms in the substance move. By contrast we have seen that gravitating systems respond to a *decrease* in energy with an increase in the speed!

This removal of energy by an escaping particle not only causes the remaining stars to speed up; just as with the planet which moves closer to the Sun after being slowed down, the stars in the system move closer together. Thus the effect of escaping stars is to make those that remain crowd into a smaller space. Indeed a similar process occurs even if stars do not escape. Relaxation causes stars to leave the dense central parts of a stellar system on the relaxation time scale, and, as a result, the central parts contract and become denser (figure 2), and the motions there become faster. As the central part of a stellar system is called the 'core', this process is called 'core collapse'. The time of relaxation in the core decreases as the core collapses, and the collapse accelerates as it proceeds. Even so it is a very gentle and slow collapse compared with that shown in figure 1, because the ratio of time scales $t_{\rm rh}/t_{\rm ff}$ is of order $N/\log N$, which is large for a rich stellar system. The process is faster if stars of different mass are present; and by a process known as *mass segregation*, which is an effect of two-body relaxation, the more massive stars settle into the core more rapidly

The resulting 'runaway' is sometimes referred to as the 'gravothermal catastrophe', but it is not very catastrophic: the rest of the system hardly notices what

Copyright © Nature Publishing Group 2001

is taking place in the tiny core. The word 'gravothermal' means that the collapse is governed by the way in which self-gravitating systems respond to loss or gain of heat.

Dense stellar systems

When the core reaches a high enough density, other processes intervene and halt the collapse. These usually involve three- and four-body interactions, either between a BINARY STAR and a single star, or between two binaries. If the system initially contained many binaries, they would settle to the core more rapidly than other stars, by mass segregation. Even if there were no binaries, interactions involving three single stars would create binaries (one of the stars being needed as a catalyst to carry off some energy).

From a gravothermal point of view the importance of these reactions is that they are a source of heat (see the article on the THREE-BODY PROBLEM), and this eventually balances the flow of heat by two-body relaxation into the outer parts of the system: this is how core collapse is halted. Henceforth the system retains a dense core, though in certain situations the balance in the flow of energy is achieved only sporadically, and the core may exhibit large-scale oscillations (figure 2). Like core collapse itself, they are gravothermal in nature.

At these high stellar densities in the core, and in the presence of binary stars, one can no longer entirely treat the stars as point masses. Real stellar collisions can, and indeed must, occur in large numbers in many dense stellar systems in nature. These processes are genuinely dissipative (though the loss of energy is not thought to be important for the energy balance of the system as a whole). Their importance is that they can modify the kinds of stars seen in dense stellar systems, and affect the efficiency of the binary interactions which are needed to maintain the system against further core collapse.

After core collapse the evolution of the system is determined by the loss of mass, through escaping stars. In realistic situations, all the mass is lost after a few tens of relaxation times.

Stellar Activity

Energy deposited in the tenuous gas above the visible surface (i.e. photospheres) of stars leads to a range of phenomena collectively referred to as stellar activity. The energy deposition heats the gas producing chromospheres, at temperatures $\sim 10^4$ K, and coronae with temperatures from a few to tens $\times 10^6$ K. The intermediate temperature region is generally called the transition region. These parts of the STELLAR ATMOSPHERE are particularly prominent in the x-ray and ultraviolet spectral regions where emission from the stellar photosphere is weak. Stellar activity is seen for a wide range of types of star, and occurs on dwarf stars with spectral types from F through M. Stellar activity is directly related to the presence of subphotospheric convection and the generation of a magnetic field by dynamo processes(see DYNAMOS: SOLAR AND STELLAR). The stellar rotation rate is also a key controlling parameter (see STELLAR ROTATION ON THE MAIN SEQUENCE). The heating processes are primarily magnetic, with acoustic energy deposition playing a minor role. The strength of the magnetic fields in the photosphere can be large (several kilogauss) and this field is associated with large starspots and the occurrence of large flares (see SOLAR–STELLAR CONNECTION). For the most active stars the energy radiated from chromospheres/coronae and liberated by flares can be at least a thousand times larger than seen in the solar atmosphere. Stellar activity is particularly intense in CLOSE BINARY STARS where rapid rotation is imposed by tidal interaction. Evolved F, G, K and M stars all possess chromospheres but coronae become weaker or absent for the cooler giants and supergiants and stellar mass loss becomes much more significant.

Stellar Astronomy (to the Rise of Astrophysics in the Mid-Nineteenth Century)

Variable stars

According to ARISTOTLE, whose world picture dominated Greek, Islamic and Western Latin civilizations until the seventeenth century, the celestial region of the COSMOS—the Moon and beyond—is unchanging except for cyclic motions that return the celestial bodies to their original positions. Changes in the brightnesses of stars were therefore deemed impossible, and so VARIABLE STARS went unnoticed. Even reports of SUPERNOVAE are excessively rare, until a bright star-like object appeared in Cassiopeia in 1572. Many observers considered it atmospheric, but the young TYCHO BRAHE was able to show convincingly that it was celestial. The possibility of change among the stars was established beyond doubt by the appearance of a second (super)nova in 1604, in Ophiucus.

Meanwhile the Frisian astronomer DAVID FABRICIUS claimed that a less dramatic new star had appeared in Cetus in 1596. Another nova appeared and disappeared in CETUS in 1638; but this time the star reappeared, and in due course was identified with Fabricius's nova. In 1667 ISMAEL BOULLIAU showed that although Mira Ceti ('the wonderful star in the Whale') was not always at the same brightness when at maximum, its maxima did occur at regular intervals of 11 months, and to this extent the variable was predictable. Boulliau also offered a physical explanation, by analogy with sunspots: the star had dark patches and its light diminished cyclically when these patches were presented to the observer as the star rotated; but just as sunspots varied, so the dark patches varied, and this resulted in irregularities in the light curve of the star.

Claims to the discovery of variables were by now commonplace. But such claims were almost impossible to verify or refute, and so interest in variable stars lapsed, until late in the eighteenth century. Beginning in 1796, William Herschel provided a means of testing whether a star was varying, by publishing extensive 'catalogues of the comparative brightness of the stars', in which each star was compared with others of almost the same brightness; any change would then disturb the published comparisons. By using much simpler sequences of stars arranged by brightness, two young English amateur observers, Edward Pigott and John Goodricke, had already detected four stars whose periods were measured in days. The first of these, Beta Persei (ALGOL), had long been reputed to vary, and after monitoring the stars for some weeks, on 28 December 1782 the two friends saw it brighten from third (or fourth) magnitude to second, before their very eyes. Pigott suspected at once that Algol was being periodically eclipsed by a planet; but eventually the friends abandoned this explanation, perhaps because of apparent irregularities that in fact were caused by changes in viewing conditions, but perhaps because no such explanation was possible for the other variables they discovered, two of which were Cepheids. Thereafter study of variables made little progress until the development of astrophysics.

Proper motions and the solar apex

By the later seventeenth century RENÉ DESCARTES had persuaded most astronomers that the stars were simply distant suns, and Isaac NEWTON concluded that stars were isolated bodies free to move in seemingly empty space. But it was not until 1718 that Edmond Halley, who was studying ancient star catalogs for a new determination of precession, was able to announce that three bright stars were no longer in the places they had occupied in antiquity. However, it would be some decades before proper motions were determined in any quantity: John Flamsteed's great star catalog, published in 1725, had been compiled just before JAMES BRADLEY's discovery of aberration and nutation (see below), and so accurate past positions of stars were unavailable in the mid eighteenth century.

Bradley himself pointed out that such motions could arise either from the motion of the solar system or from movements of the stars themselves, and Tobias Mayer in 1760 argued that *patterns* of proper motions should be ascribed to the former and *deviations from patterns* to the latter. The first to detect such a pattern was William Herschel (see HERSCHEL FAMILY). Working with far from reliable data, he proposed in 1783 that the solar system was moving towards Lambda Herculis, close to modern determinations. For reasons as yet unexplained, F W Bessell, after reducing Bradley's star observations for his *Fundamenta astronomiae* (1820), was unable to find any such pattern. But in 1837 F W A Argelander published the results of an investigation into no fewer than 390 proper motions, a number large enough for him to divide them by size into three groups which he treated independently; each yielded an apex not far from that proposed by Herschel. The matter was put beyond dispute in 1847 when Thomas Galloway analysed proper motions of southern stars not previously taken into account, and derived a similar apex.

Distances of stars

In the cosmologies of Aristotle and Ptolemy, the stars were located immediately beyond the outermost planet. When Copernicus in 1543 argued that the Earth orbits the Sun and that we therefore observe the stars every six months from opposite ends of a diameter of the Earth's orbit, opponents demanded to know why no annual parallaxes had been detected. By the later seventeenth century, after Kepler had taught astronomers to see the massive Sun as the centre of the planetary system, annual parallax had developed into the hoped-for means of determining the distances of stars. But if Descartes was right and the stars were physically the equal of the Sun, their distances must be vast, and the detection of annual parallax with instruments subject to shrinking and warping with the passage of the seasons was a daunting task. However, if the brightness of a star (such as SIRIUS) could be compared

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

with the brightness of the Sun, then since light diminishes with the square of the distance this ratio could be converted to a ratio of distances. The best-known attempt at this comparison was by CHRISTIAAN HUYGENS, in his posthumous COSMOTHEOROS (1698). Huygens viewed the Sun through a pinhole made in a screen, hoping that the fraction of the Sun that was thereby visible would be equal in brightness to Sirius. The technique was clumsy, but his conclusion, that Sirius lay at 27 664 astronomical units, showed that the scale of interstellar distances was vast.

A much better method was advanced by JAMES GREGORY in 1668, in a little-noticed work on geometry. He proposed replacing Sirius by a suitable planet, at a time when the planet was of the same brightness as Sirius; the required ratio was then equal to the ratio of the light received directly from the Sun, to the light received from the Sun via the planet. This calculation had the merit of involving only quantities related to the solar system. Even when working with values that he knew to be obsolete, Gregory placed Sirius at 83 190 AU; the true distance would be much greater, in fact about 10^6 AU according to Newton when drafting *The System of the World* around 1685. But this work appeared only in 1728, after Newton's death, and until then his estimate was known only to his intimates.

Meanwhile a remarkable attempt to measure annual parallax was made by ROBERT HOOKE. The known hazards in the way of such measurements were the possible warping of the instrument with the change of the seasons, and the uncertain effect of refraction. The latter problem Hooke sought to overcome by selecting as his target GAMMA DRACONIS, a star that passed directly overhead his home in London; the former, by incorporating the tube carrying the object glass into the fabric of the roof of his house. The resulting zenith telescope was designed to resolve one single problem (stellar parallax), by observing one single star but only when the star was specially positioned: a remarkably mature use of a scientific instrument. Unfortunately, Hooke made only four observations before the object glass broke, and his claims to have detected parallax were discounted by other astronomers. But his method was promising, and it was revived in 1725 by an English amateur, Samuel Molyneux, who commissioned a zenith telescope from George Graham. His collaborator, James Bradley, found the movements of Gamma Draconis were three months out of phase from those expected from annual parallax. Commissioning a second instrument with a wider field of view, Bradley was able to establish the pattern of movements displayed by a number of stars. Later, the explanation came to him: the speed of light, though great, is finite, and the apparent position of a star is affected by the velocity of the observer on Earth.

The discovery of 'the aberration of light' was proof of the motion of the Earth around the Sun. It also revealed an unexpected error in all existing star catalogs, including Flamsteed's. And because Bradley had failed to detect annual parallax, he could estimate from the accuracy of his measures that the stars must be at least 400 000 AU from the Sun. His publication in 1729 of this *minimum* distance of stars was fully compatible with Newton's estimate of the actual distance of Sirius, based on the hypothesis that Sirius and the Sun were physically equal; and the appearance of these two results within a few months of each other convinced astronomers that light even from the nearest stars took several years to arrive on Earth.

Not surprisingly, it was decades before attempts to measure such tiny annual parallaxes were resumed, and even then successive claims proved to be mistaken. It was essential to single out for measurement the stars that were nearest to Earth, and an important advance came in 1837 when WILHELM STRUVE at Dorpat published an assessment of the relevant criteria. By now proper motions were available in quantity, and there was evidence—for example from binary stars—that apparent brightness was an unreliable guide to distance. Stars with large proper motions could more confidently be taken to be near, and Giuseppe Piazzi and BESSEL had both drawn attention to 61 CYGNI, 'the flying star'. Also, the craftsmanship of Joseph Fraunhofer had equipped both Bessel at Königsberg and Struve at Dorpat with precision instruments of a quality hitherto unavailable.

In 1835 Struve selected VEGA for study. The star was bright and had a large proper motion, and in 1837 he deduced from 17 observations a parallax of one-eighth of a second of arc. Encouraged by Struve's apparent success, Bessel subjected 61 Cygni to a year's scrutiny, observing the star many times on the same night, and at the end of 1838 he announced a parallax of about one-third of a second of arc. Bessel's many observations closely matched the pattern predicted from theory, and it was this that convinced astronomers that a genuine measure of parallax had at last been achieved.

Double stars

Struve and Bessel had used distant stars as reference points against which they measured the motions of the stars under examination, and in doing this they had been applying a method proposed by GALILEO in 1632 to facilitate the measurement of annual parallax. Galileo understood very well the immense practical difficulties involved in tracking tiny stellar movements spread over many months; however, if the star under investigation chanced to lie in almost the same direction as another and much more distant star (so that the two formed a 'DOUBLE STAR'), the distant star could act as a quasi-fixed reference point provided by a helpful Nature.

Characteristically, Galileo himself did nothing to follow up this insight, nor did any observers prior to William Herschel. In the late 1770s, Herschel was systematically familiarizing himself with the brighter stars, and he took the opportunity to watch out for double stars. In 1782 and 1785 he published two catalogs of doubles totalling 703 specimens.

However, unknown to Herschel, John Mitchell had published a paper in 1767 in which he pointed out that the number of double stars was far greater than would be expected if the doubles occurred merely by

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

chance: most of them must be neighbors in space, lying at the same distance from Earth and therefore useless for the measurement of parallax. And when Herschel re-examined some of his doubles after an interval of two decades, he found several instances in which the two stars had indeed orbited around each other. But was the force that bound them together in fact gravitational attraction, as everyone assumed? To decide this, more details were needed of the orbits. At length, in 1827, Félix Savary was able to confirm that the two stars of Xi Ursae Majoris did indeed move in elliptical orbits about their common centre of gravity, as Newtonian theory required. Newton himself had assumed that gravitational attraction was a universal force; now there was at least proof that it operated among the stars.

The system of the stars and the darkness of the night sky

Despite these various developments in the theory of certain individual stars, until the rise of astrophysics in the later nineteenth century the stars as a whole remained little more than a backcloth to the motions of the bodies of the solar system. Even Newton in the *Principia* displays almost no interest in the stars, and this despite his claim that gravity was a universal force: for forces cause movements, and if each star was being attracted by every other star then it was far from obvious how every single star continued (as it seemed) to rest motionless in the position recorded for it in the star catalogs of antiquity. Although Newton had a better understanding of the immensity of interstellar distances than any other living person, it did not occur to him that the stars might indeed be in motion, but that because of their remoteness their motions had not yet been detected. Perhaps he was mesmerized by his own use of the traditional Latin *stella fixa* as the term for 'star'. At all events, when challenged to expound his cosmology he attempted to reconcile the immobility of the stars with the universality of gravity by arguing that the system of the stars was infinite and almost symmetric. This being so, each star was being pulled almost equally in every direction by the other stars, and therefore remained (almost) at rest.

However, the symmetry (which he defended by comparing the numbers of stars predicted from a theoretical model with the numbers found in star catalogs) is clearly not perfect, and Newton accepted that in the long term the stellar system would be threatened with gravitational collapse. How could this be reconciled with the accepted image of God as the great clockmaker? Descartes had portrayed a God who created the universe, set it in motion, and then abandoned it to run itself. Newton, by contrast, believed that God must display a continuing concern for the welfare of his creation. He had revealed himself not only through the Book of Scripture but also through the Book of Nature. The scientist investigating the star system and uncovering its near symmetry (and therefore medium-term stability) learned from the Book of Nature the concern for mankind that God had displayed at the creation. And God displayed an on-going concern for mankind by intervening whenever gravitational collapse threatened, and restoring the original order. G W Leibniz condemned this conception as portraying God as a bungling clockmaker who resorted to miracles to repair bad workmanship; Newtonians replied that these divine interventions were not miracles, but regular acts foreseen from the beginning. Both parties agreed that the structure of the stellar universe was essentially permanent and would show no development with time.

About 1720 a young physician, William Stukeley, in conversation with Newton, diverted the discussion away from the consequences of gravity and towards consideration of the cumulative light of infinitely many stars. If the star system was infinite, he argued, the whole sky would have 'the appearance of that luminous gloom of the milky way'. In 1721 EDMOND HALLEY breakfasted with Stukeley and Newton and discussed astronomical topics, a few days before Halley read two short papers on cosmology to the Royal Society in which he remarked: 'Another Argument I have heard urged, that if the number of Fixt Stars were more than finite, the whole superficies of their apparent Sphere would be luminous.' Halley offered a defective defence of the infinity of the stars, but the publication of his papers brought the Newtonian universe—anonymously—into the public domain.

In 1744 the Swiss astronomer J-P L de Chéseaux showed that even if only a tiny fraction of starlight was lost in traveling the distance from one star to the next, the cumulative effect of these losses would be decisively to reduce the total amount of light received from the innumerable stars at great distances. That is, the darkness of the night sky was no obstacle to belief in the infinity of the stars. Much the same argument was advanced in 1823 by H W M Olbers, and it is his name that has become attached to the so-called 'OLBERS' PARADOX', though nineteenth-century astronomers found no difficulty in offering a variety of explanations for the darkness of the night sky.

The Milky Way

The MILKY WAY GALAXY was, one might think, a decisive disproof of Newton's claim that the system of the stars is symmetric, but his lack of interest in this phenomenon was typical of his generation. Serious astronomers were preoccupied with the solar system, and it was only after a group of speculators in the mid eighteenth century proposed explanations of the Milky Way that the problem of the structure of the stellar system began to enter mainstream astronomy.

The first of these speculators was THOMAS WRIGHT of Durham, a self-taught itinerant lecturer. In 1734 he prepared a public lecture on cosmology in which the stars were portrayed as occupying a spherical shell of space that surrounded the Divine Centre, the region beyond the shell forming the Outer Darkness. As the stars could not be permitted to fall into the Divine Centre, each was in

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

(circular) orbit within the shell. Wright illustrated his lecture with a representation of a cross section of the universe, in which he also showed how his stellar system would appear from Earth, which of course was a planet of one of the stars within the shell. The light of the numerous stars within the cross section that were distant from Earth but still visible to humans would, he argued, merge to give the effect of a milky circle in the sky. He thought he had thereby explained the Milky Way, until he realized that the plane of the Milky Way is unique whereas the plane of his cross section was arbitrary.

Having considered the matter further, in 1750 Wright published *An Original Theory or New Hypothesis of the Universe*, with two alternative explanations of the Milky Way. In the preferred alternative the Sun was, as before, a member of a spherical shell of stars that surrounded what was now one of many Divine Centres. But now the shell was thin, and of vast diameter, so that an observer facing inwards or outwards would see only a few stars (which were near and therefore bright) before looking into empty space. But when facing tangentially to the shell, the observer would see great numbers of stars, whose light would merge to give the effect of the Milky Way. The plane of the Milky Way, therefore, was the tangent plane to the shell of stars at the place where the terrestrial observer was located.

An alternative explanation saw the system of stars as forming a broad, flat ring surrounding the (local) Divine Centre, in which case the *visible* stars would occupy a disk-shaped region of space internal to the ring. The observer looking in any direction within the plane of the ring would see innumerable stars whose light would merge to give a milky effect.

Wright disliked the second model because he had no explanation for the particular plane of the ring, but both models were described in a summary of his book (but without illustrations) that was published the following year in a Hamburg periodical. This came to the eyes of the young IMMANUEL KANT, who, misunderstanding Wright, thought the Divine Centre was elsewhere in the universe. This being so, he saw no reason why the ring should not extend continuously from one side to the other, so that the system of the stars would occupy a space whose shape was not that of a hollow ring but of a disk. He also knew of observations by P L M de Maupertuis, which Kant interpreted as being of other star systems that had an elliptical outline. A spherical system viewed from without will always have a circular outline, but a disk-shaped system will appear elliptical. Kant therefore adopted Wright's second model, as duly modified, and he concluded that our star system is disk-shaped.

Wright's book had limited circulation, distribution of Kant's work was undermined by the bankruptcy of the bookseller, and a work by J H Lambert, an Alsatian living on the fringes of the scientific community and who had somewhat similar ideas, also found a limited public. It may well be, therefore, that when William Herschel turned his attention to the problem of the Milky Way, he was unaware of these earlier speculations. Herschel took it for granted that the Milky Way was the optical effect of our immersion in a layer of stars, and he saw that he could establish the detailed shape of the layer if he allowed himself two assumptions. The first, obviously, was that his telescope could penetrate to the borders of the system in all directions, for unless this was so his quest was hopeless from the start. The second was that within the borders of the space occupied by stars, the system was roughly symmetric. Obviously this was by no means strictly true; Herschel hoped that it would be true enough for his purpose.

Granted these assumptions, the number of stars visible in any particular field of view of Herschel's telescope would be directly proportional to the volume of space within the Galaxy within that field of view, and a simple calculation would convert this volume into the distance to the border in that direction. Herschel did not have time enough to carry this pioneering exercise in stellar statistics to a conclusion, but in 1785 he completed the examination of a great circle of the sky and converted the resultant star counts into a cross section of the Galaxy.

The experience of later years convinced him that neither assumption was even approximately correct. His 40 ft reflector completed in 1789 revealed many stars hitherto hidden from him, and his studies of nebulae and clusters showed how very non-uniform is the distribution of the stars of the Galaxy. He therefore abandoned his cross section of the Galaxy, but as for many decades nothing comparable was advanced to fill its place, the diagram continued to appear until late in the nineteenth century.

The riddle of the nebulae

This investigation, however, was a distraction from the great campaign to which Herschel had dedicated himself, a systematic search for NEBULAE and clusters. Mention of nebulous stars goes back to antiquity, but much-needed clarity was introduced into the subject by Halley in 1715 when he published a list of six nebulae; these he believed to be formed of a 'lucid medium'. Others, however, adopted the simpler view that a nebula was a star cluster so distant that the individual stars could not be distinguished. Observations could help settle the issue in two ways. First, new and bigger telescopes might resolve into stars objects that had appeared nebulous in lesser instruments. Second, if it was shown that a nebula had changed in appearance over a few years or even decades, then the nebula could not be a distant and therefore vast star system, for the widely scattered components of such a system would not have been able to travel such great distances in so short a time. Herschel shows an awareness of this latter consideration on the very first page of his first observing book, dated March 1774. For the rest of that decade he was able to make only occasional observations of a single nebula, the ORION NEBULA, but these were enough to satisfy him that it was indeed altering shape. This being so, it must be a true nebula.

How then to distinguish between true nebulae and distant star clusters? Herschel decided that true nebulae revealed themselves by their smooth, milky appearance, while distant star clusters had a mottled look. But no sooner had he proposed this in a 1784 paper to the Royal Society, than he came across two nebulae in which both forms of nebulosity were intermingled. This forced him to reinterpret the evidence. He now decided that mottled nebulosity indicated stars at middle distance, while milky nebulosity indicated stars further away. All nebulae were systems of stars.

In 1783 he had embarked on a systematic search for nebulae. With his 20 ft reflector facing south, he allowed the sky to drift past as he waited for a nebula to come into view; he would then shout out details of its appearance to his sister Caroline who was seated at a desk at an open window nearby. In 20 years of observing, the team of brother and sister collected 2500 nebulae, to add to the hundred or so listed by Charles Messier in 1781. They thereby introduced into astronomy the methodology of the natural historian, for they were collecting and classifying specimens in great numbers. Furthermore, Herschel realised that since gravity was a universal force, a scattered star system would become more concentrated as time passed. This allowed him to develop a cosmogony, set out in papers published in 1785 and 1789. He envisaged the process as beginning with widely scattered stars; then, as time passed, the gravitational pull of the stars that happened to be in greater concentrations than elsewhere would draw in the surrounding stars, leading to the formation of systems of ever increasing density. Where Newton had seen in the heavens the stability of clockwork, Herschel saw development analogous to that of the life-story of a person.

In November 1790 Herschel was 'sweeping' as usual when he came across NGC 1514, which he saw as a star surrounded by a luminous halo. He had already seen several 'PLANETARY NEBULAE' as he termed them, objects that had planet-like disks but shone with the pale light of a nebula, and he was greatly puzzled by them. To modern astronomers NGC 1514 is another planetary nebula, but to Herschel it was a 'nebulous star'. Indeed, it was a star that was condensing out of the nebulosity that surrounded it. Clearly, (true) nebulosity existed after all.

Herschel thus found himself forced to alter his opinion once more. In papers published in 1811 and 1814, he extended his earlier cosmogony back in time, before stars had formed out of the diffuse nebulosity; he described the formation of concentrated nebulous clouds, out of which stars condensed, which in turn developed into more and more tightly packed clusters.

William Herschel was in his fifties when his son John was born, and in his late seventies when John embarked on a career as a Cambridge don. Eager to transmit his skills and experience while he still had strength, William prevailed upon John to return home and become in effect his apprentice. Late in 1820 William's 20 ft reflector deteriorated to the point where John undertook the construction of a replacement; and with this in 1821 he carried out two trial sweeps, with his aged aunt as his mentor. In 1825, after his father's death, he commenced a systematic re-examination of his father's nebulae. Unfortunately William's catalogs of nebulae were arranged by type and so quite unsuited to John's needs. Caroline, by now living in her native Hanover, came to the rescue, and undertook the immense labor of rearranging the catalogs into a form suitable for 'sweeping', a task for which she was awarded the Gold Medal of the Royal Astronomical Society.

John's re-examination of the northern nebulae resulted in a catalogue of 2306 nebulae and clusters published in 1833. John then set sail for the Cape of Good Hope, and in four years of intense activity extended to the southern skies all aspects of his father's researches. His *Results of Astronomical Observations Made ... at the Cape of Good Hope*, published in 1847, listed over 1700 nebulae and clusters and over 2100 double stars, as well as thousands of star counts and much else besides.

Whereas his father had left no one in any doubt as to his opinions, John was more circumspect, and sometimes inhibited by his reluctance publicly to differ from his father. Meanwhile the debate continued: were all nebulae star clusters that appeared nebulous simply because they were so distant, or were some star clusters and others truly nebulous? Because of its brightness and apparent size, the Orion Nebula became a test object: could it, or could it not, be resolved into stars under examination by a truly massive reflector?

In 1839, at his estate at Birr Castle in central Ireland, William Parsons (the future THIRD EARL OF ROSSE) succeeded in building a reflector on the Herschelian model, with a segmented mirror 3 ft in diameter; the following year, he cast a solid mirror of the same size. He persuaded himself that the instrument had resolved into stars a number of prominent nebulae, and he determined to build a still bigger instrument, with mirrors no less than 6 ft in diameter, to carry this process to a convincing conclusion. The 'Leviathan of Parsonstown' first saw light in February 1845, and within a few weeks Rosse was able to announce that the nebula M51 had a spiral structure. A year later, he claimed decisive evidence of the resolvability of the Orion Nebula, a feat that many saw as proclaiming the end of belief in 'true' nebulosity. Rosse has been criticized for seeing what he wanted to see, but in fact his great reflector was capable of seeing stars that are indeed embedded in the nebula, and it is not surprising that he interpreted this as evidence that the nebula is stellar.

There were, however, doubters, notably observers who believed they had seen changes in nebulae, changes that had happened too quickly for the nebulae to be vast stellar systems. This seemed indisputably the case when a nebula discovered in 1852 by John R Hind completely disappeared in 1861. Three years later, the new techniques of astrophysics brought the long debate to a conclusion, when William Huggins demonstrated beyond argument the existence of gaseous nebulae.

Stellar Atmospheres

The atmosphere of a star is the boundary between the stellar interior and the interstellar medium. It spans the layers from which photons can escape to the surrounding space. Direct information about the physical state of the stellar atmosphere can therefore be derived from the emergent radiation. This is, however, not the case for deeper layers, because photons that are emitted in these layers are reabsorbed or scattered numerous times before escaping. A physical description of the stellar interior can be inferred only indirectly: the atmosphere as a boundary layer reflects the conditions in the stellar interior. The only direct probes of the stellar interior are neutrinos emitted in the core and gravitational waves, but there are considerable difficulties in detecting them (only neutrinos emitted by the Sun and SN 1987A have been observed so far). In the last decade, helioseismology has developed very rapidly, and the study of numerous oscillation modes has allowed us to probe the Sun's interior. Asteroseismology will follow in the coming years, but the very low amplitude of stellar oscillations has limited its current application to pulsating stars. Therefore, our present understanding of stellar structure and evolution hinges primarily on our ability to model stellar atmospheres and on analysing the emergent radiation.

This article describes stellar atmospheres very broadly. It discusses the general structure of stellar atmospheres, line formation, stellar atmosphere theory, opacities and non-thermal phenomena. More details can be found in the articles on STELLAR ATMOSPHERES: COOL STARS, STELLAR ATMOSPHERES: EARLY-TYPE STARS, EXTENDED ATMOSPHERES, CHROMOSPHERE, CORONAE and the SOLAR WIND.

General structure

The atmosphere might be quite extended in space. However, the bulk of the radiation is emitted in a thin layer, the *photosphere*. The solar photosphere is about 600 km thick as illustrated in figure 1. Hotter stars have thicker photospheres, but in general the extent of the photosphere corresponds to about 1/1000 of the stellar radius.

The structure above the photosphere differs markedly between cool and hot stars. Cool stars (spectral type A7 and later on the main-sequence, or $T_{\rm eff} < 7500$ K) are characterized by increasing temperature in their outer layers. Figure 1 illustrates the temperature structure of the solar atmosphere. The *chromosphere*, with typical temperatures ranging from 7000 to 20 000 K, is diagnosed from emission lines in the far-ultraviolet and emission reversal in the core of very strong optical lines (Hα, Ca II H and K). Above the chromosphere, there is a

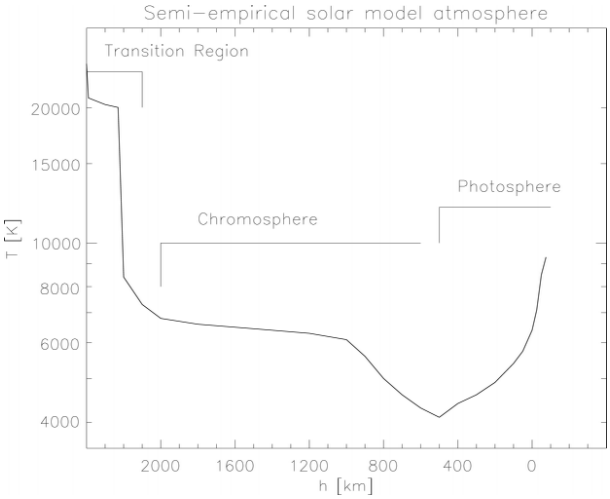

Figure 1. Semi-empirical temperature–height distribution for the average, quiet Sun (adapted from Vernazza *et al* 1973 *Astrophys. J.* **184** 605), illustrating the general atmosphere structure of late-type stars. The origin of the height scale corresponds to optical depth unity, and the solar interior is to the right.

hot, million-degree *corona* seen in solar eclipses and detected in the x-ray and extreme ultraviolet domains by various satellites. Obviously, there is also a transition region between the chromosphere and the corona with intermediate temperatures where emission lines of ionized species like He II, C IV and Si IV are formed. While the exact heating mechanism(s) of the chromosphere and corona are not yet fully understood, chromospheres and coronas have been detected only in low-mass stars having a sub-photospheric convection zone.

Strong, fast *winds* typify the atmospheres of early-type main-sequence stars (O and early B-type) and O, B and A-type supergiants. The characteristic spectral features of these winds are strong P-Cygni line profiles and an infrared excess due to free–free emission in the wind. These fast, supersonic winds are driven by radiation pressure generated by absorption of photons in spectral lines. X-ray emission has also been detected in O and early B-type stars, but this is not a signature of a corona. This emission is attributed to shock-heated material in the wind.

Winds are also present in cooler stars. In cool main-sequence stars, the high coronal temperature results in a large gas pressure inducing a weak pressure-driven stellar wind. This is a fast wind, but so tenuous that it is optically thin throughout and cannot be detected spectroscopically. In this respect, this wind is not really a part of the stellar atmosphere as defined. In evolved cool stars, a much denser wind is observed. Due to the low surface gravity of such stars, the mass loss rate of a coronal wind would be larger, but other mechanisms like radiation pressure on dust grains formed in the outer

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

layers or like acceleration in pulsating layers become more efficient drivers. In contrast to the winds of cool main-sequence stars, the winds of red supergiants are slow.

Atmospheric parameters

For most stars, a radius, R, can be defined quite naturally by the distance of the photosphere from the center of the star. The total luminosity, L, radiated by the star is given by

$$L = 4\pi R^2 \int_0^\infty F_\nu \, \mathrm{d}\nu = 4\pi R^2 \sigma T_{\mathrm{eff}}^4 \tag{1}$$

where the flux integral is the total radiated power per unit area. The *effective temperature*, T_{eff}, is defined in an analogous form of the Stefan–Boltzmann law, making T_{eff} the temperature of a black body radiating the same energy per unit area as the star. The stellar spectrum may, however, differ dramatically from a black body spectrum. From this relation and the limited extension of the photosphere, it follows that the electronic temperature in the photosphere is typically of the order of the effective temperature. This temperature is the first fundamental parameter describing a stellar atmosphere.

Apart from the temperature, the emergent spectrum will reflect the density of the absorbing and emitting material in the photosphere. The total mass density in the photosphere is set by the balance between gas and radiation pressures on the one hand and gravity on the other. The gravitational acceleration, $g = GM/R^2$, is constant since the photosphere is a thin layer (M is the mass of the star). The *surface gravity* is thus the second fundamental parameter, and is usually expressed as $\log g$, in cgs units. Absorption and emission processes will also depend on the chemical composition of the atmosphere, which is the third major parameter. Additional parameters may be defined to describe an atmosphere, e.g. turbulent velocities, magnetic field strengths or wind parameters.

Geometry

Because the radial extent of the photosphere is much less than the stellar radius (i.e. the curvature is mostly negligible), most stellar photospheres can be modeled like plane-parallel slabs. The scale height is the characteristic distance on which pressure and density decrease in the slab, and thus depends on the surface gravity. Spectroscopic analyses of the photospheric spectrum with plane-parallel model atmospheres therefore yield an estimate of $\log g$, but do not provide the stellar radius directly.

There are, however, some important cases, like supergiants and Wolf–Rayet stars, for which the geometrical extension of the photosphere becomes comparable to the stellar radius. This makes any definition of the radius much less obvious, and parameters like T_{eff} and $\log g$ lose much of their meaning if a radius is not defined properly. Usually, the radius is defined as the distance from the center where the mean Rosseland optical depth reaches unity (see the discussion on the gray case later in this article), and the spectrum provides direct information on the stellar radius. A spherical geometry must be assumed to model these stars.

General theory

A physical theory providing a description of the structure of a stellar atmosphere will essentially express how energy is transported from the stellar interior (where it is generated by nuclear reactions) through the atmosphere (to be radiated in the interstellar medium). Radiation is the major mode of energy transport through the surface layers. In cool stars with sub-photospheric convective zones, convection carries a significant fraction of the energy in the deep photosphere. However, in upper layers, convection becomes rapidly inefficient. A hot convective cell rising from deeper layers will quickly radiate all its extra energy and reach an equilibrium with the local gas. Some spectral features are nonetheless sensitive to convection and are used to check convection theories. At much lower densities, as in the solar corona, heat conduction becomes an important process. In the upper atmosphere, energy may also be transported by MHD or acoustic waves that are responsible for heating the corona non-radiatively. These waves have been generated by strong and geometrically complex magnetic fields, which in turn are created by a dynamo effect in the convection zone (see the section on non-thermal processes later).

Radiation therefore not only probes the physical conditions in stellar outer layers, but is a major constituent that structures the whole atmosphere. It is a non-local process that drives the atmosphere away from thermodynamic equilibrium (as we see a star, there are energy losses). Because non-equilibrium situations are always difficult to model, a number of simplifications have historically been made to describe the geometry, the dynamics and the thermodynamics of stellar atmospheres. Early models assumed one-dimensional geometry (plane-parallel slab, spherical symmetry), a static medium, *local thermodynamic equilibrium* (LTE) and a frequency-independent opacity (gray atmosphere). Some of these assumptions have since then been lifted to model different stellar types (e.g. departures from LTE are especially important in hot stars), but the full 3D, non-LTE, radiation-hydrodynamics problem still remains intractable. The main emphasis was first put, on the one hand, on LTE metal line-blanketed model atmospheres incorporating the detailed opacity of millions of atomic lines, and on the other hand on non-LTE model atmospheres with much fewer opacity sources. Later, the emphasis shifted to non-static models to interpret the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

observations of stellar winds. In recent years, non-LTE metal line-blanketed models have been developed for static photospheres and stationary winds. Solving the non-LTE radiation hydrodynamics problem with detailed opacities and constructing multidimensional non-LTE model atmospheres are major avenues of research today.

Radiation transport

While radiation transport may be expressed most generally by the kinetic (Boltzmann) equation for photons (similarly to the case of massive particles), it is more customary to derive the radiative transfer equation phenomenologically. Let us consider radiation traveling in a direction s. The specific intensity I_ν is the amount of energy transported by units of surface, solid angle, time and frequency. Along the path s, the change in specific intensity, $\mathrm{d}I_\nu/\mathrm{d}s$, is the sum of the energy losses and sources:

$$\mathrm{d}I_\nu = -\kappa_\nu I_\nu \,\mathrm{d}s + j_\nu \,\mathrm{d}s \tag{4}$$

or

$$\mathrm{d}I_\nu/\mathrm{d}\tau_\nu = -I_\nu + S_\nu \tag{3}$$

where the *source function*, S_ν, is the ratio of the emission and absorption coefficients, and $\mathrm{d}\tau_\nu = \kappa_\nu \,\mathrm{d}s$ is the *optical depth* along the radiation path. The absorption coefficient, κ_ν, describes the removal of energy from the radiation field by matter, and the emission coefficient, j_ν, describes the energy released by the material. Thus these two coefficients describe the interaction between matter and radiation. Actual expressions are given by the microscopic state of the plasma. A more general form of the radiative transfer equation may be written by replacing the derivative along s by the total derivative ($\mathrm{d}/\mathrm{d}s \rightarrow 1/c\partial/\partial t + \boldsymbol{n}\cdot\nabla$).

The formal solution of this equation follows a standard integration. The specific intensity emerging from a slab having an optical depth τ_ν is:

$$I_\nu(0) = I_\nu(\tau_\nu)\,\mathrm{e}^{-\tau_\nu} + \int_0^{\tau_\nu} S_\nu(t_\nu)\,\mathrm{e}^{-t_\nu}\,\mathrm{d}t_\nu. \tag{4}$$

The first term expresses the attenuation of the incoming intensity and the second term is the source term. This solution, however, hides the actual difficulty of solving the radiative transfer equation. The source function contains a thermal emission term and a scattering term. The scattering term depends on the mean intensity of the radiation field (specific intensity averaged over all directions) resulting in a non-linear equation in most cases.

A numerical solution of the radiative transfer equation may be obtained by different methods depending on the complexity of the problem at hand. Equation (4) provides a formal solution if the source function is fully specified. For a long time, a direct quadrature was viewed as extremely inefficient due to the required exponentials. This limitation has mostly disappeared with present-day computers. Other methods can be divided into two main classes: first-order form and second-order form of the transfer equation. First-order methods have been recently revived by an adaptation of the discontinuous finite element method. The specific intensity is assumed to be given as a linear function of optical depth. Straightforward analytic manipulations result in simple expressions for the discretized specific intensities. The solution is obtained independently for each angle (direction) and for each frequency. The second-order method, usually known as the Feautrier method, has long been the method of choice, because it allows easy expression of the angle coupling arising from the scattering term in the source function. The basis of the Feautrier method is to introduce the symmetric and antisymmetric angle averages of the specific intensity and to combine the transfer equations in the upward and downward directions. Some simple algebra results in a second-order differential equation. With proper boundary conditions, a tridiagonal set of discretized equations is solved by a straightforward Gaussian elimination scheme.

Generally, the source function is not known fully. The source function may be written as:

$$S_\nu = \alpha_\nu + \beta_\nu \bar{J} \tag{5}$$

where α_ν describes the thermal processes, β_ν the scattering processes and $\bar{J}$ is an appropriate average of the specific intensity over angles and (line) frequencies. The details of the frequency average depend on the assumed correlation in frequency of absorption and emission processes (the so-called complete and partial redistribution functions). Scattering is mostly due to electron Thomson scattering (Compton scattering is unimportant except in the hottest atmospheres); additional scattering processes may be present. Although the source function may remain linear in the specific intensities in some special circumstances (two-level atom case), scattering introduces a coupling between the specific intensities at different angles and frequencies. The radiative transfer equation must now be solved simultaneously at a number of angles and frequencies. This coupling may easily be expressed in the Feautrier scheme and a single-step solution is still possible in the linear case. However, the Gaussian elimination scheme requires matrix inversions where the matrix size is the product of the number of angles times the number of frequencies. Nonlinear, multilevel atom problems are classically solved by linearizing the equations and iterating. The complete linearization method is based on such a Newton–Raphson method. The radiative transfer

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

is solved using the Feautrier scheme, thus taking fully into account the angle–frequency couplings. This method converges rapidly because all couplings are treated explicitly, but the computing cost quickly becomes prohibitive. An iterative method that avoids explicitly solving the coupling would thus be preferable.

The straightforward iteration method, the so-called Λ iteration, consists in solving the transfer equation by assuming a starting estimate of the source function, then recalculating the source function with the first estimate of $\bar{J}$, and then iterating. This iteration scheme has long been known to fail in the case of strong scattering (most strong resonance lines, e.g. Lyman α, C IV, Mg II). Scattering decouples the radiation field from local sources and sinks and involves global transport of photons over large distances in the atmosphere. The iteration process propagates information on the changes of $\bar{J}$ over a mean free path ($\Delta\tau \approx 1$) at each iteration. This scheme therefore requires a very large number of iterations to converge at large optical depths (and, more seriously, the solution seems to be converged while still far from the exact solution).

Recent progress was achieved upon the realization that not all the parts of the coupling should be treated on the same footing. Some parts of the coupling are more important and must be treated explicitly to ensure convergence, while the rest may be treated iteratively (as in Λ iteration). This is the basis of the method of deferred corrections that is at the heart of the accelerated lambda iteration (ALI) methods. The radiative transfer operator is split into a local part that may be easily inverted (thus solved cheaply in a single step) and a non-local correction applied to the fully specified, previous estimate of the source function. Such methods yield fast convergence and are further described in the article on RADIATIVE TRANSFER.

Opacities

Stellar atmosphere theory and spectral analyses depend heavily on atomic physics. The opacity of the atmospheric plasma is the basic physical quantity that determines the radiation transport, and thus determines the atmospheric structure as well as the emergent spectrum. The total absorption coefficient describes the interaction between radiation and matter, and depends on the chemical composition of the atmosphere and its thermodynamical state as expressed by the temperature, the electronic density and the populations of the energy levels of all species.

The total opacity includes four general contributions: the bound–bound, the bound–free, and the free–free opacity, and a scattering term (mostly electron scattering). Detailed expressions for these opacity sources may be found in Mihalas (1978). For hydrogen, analytical expressions exist for the different contributions to the opacity. For heavier elements, detailed calculations of the atomic structures are required to obtain the cross sections. Thanks to huge efforts in the last 20 years, extensive and reliable atomic data are now available. Good starting points to retrieve the necessary atomic data are the Opacity and Iron Projects which provide detailed photoionization cross sections, line transition probabilities and collisional data for the most abundant light elements up to iron, the Kurucz line list, which is widely used in stellar atmosphere modeling and spectral analyses, and the National Institute of Standards and Technology (NIST) which provides critically evaluated atomic databases (level energies, oscillator strengths) and an extensive bibliography.

With the exception of atomic level energies, the bulk of the required atomic data have been obtained theoretically. Some line transition probabilities and very few photoionization cross sections have been measured in the laboratory, in part due to the difficulty of creating the necessary physical conditions to measure them. To check the theoretical data, stellar atmospheres may provide a different laboratory where such conditions are met. This approach was mainly followed to derive oscillator strengths, matching the solar (or stellar) spectrum with model spectra. These data may be affected by systematic effects due to imperfections in the solar (stellar) model atmosphere used to compute the spectrum, but these systematic errors cancel out when performing a differential analysis (i.e. the oscillator strengths are derived from the solar spectrum and applied to the analysis of solar-type stars). Such sets of oscillator strengths are particularly valuable for chemical abundance studies.

Major effects resulting in departures from LTE are shifts of the ionization equilibria. Reliable photoionization cross-sections are therefore essential data in non-LTE model atmospheres. Detailed atomic structure calculations of atoms and ions having many electrons yield very complex photoionization cross-sections, with resonances due to autoionization processes. Available laboratory data are very limited (mostly cross sections from the ground state of neutral atoms). In this case, stellar atmospheres are not as useful for line strength, because the continuum spectrum reflects the total bound–free and free–free opacities of all atoms and ions present in the photosphere. This opacity is usually dominated by the hydrogen opacity because hydrogen is the major constituent of the atmosphere. In the presence of strong chemical anomalies, the total opacity may be dominated by other opacity sources. This is particularly the case in the far-ultraviolet spectrum of silicon-rich Ap stars. The bound–free Si II opacity becomes dominant, and the observed spectrum reflects these cross-sections. Figure 2 displays the UV spectrum of the ApSi star HD 34452. The observations are compared with theoretical spectra calculated with new

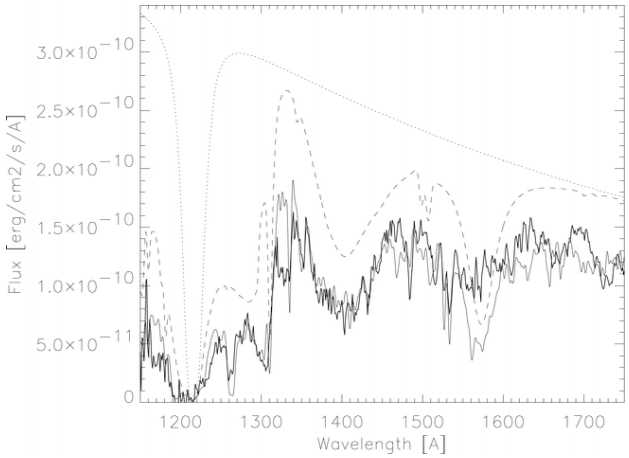

Figure 2. IUE low-resolution spectrum of HD 34452 (thick curve) compared with a theoretical spectrum synthesis (thin curve). Continuum spectra (H + C: dotted curve; H + C + Si^+: broken curve) are also shown to illustrate the huge effect of Si II autoionization resonances (from Lanz *et al* 1996 *Astron. Astrophys.* **309** 218).

cross sections computed with the *R*-matrix method. The atomic data calculations are very similar to those of the Opacity Project. The model spectrum reproduces very well the positions and widths of the broad autoionization resonances, and therefore provides supporting evidence of the reliability of this set of atomic data. Additional evidence of the quality of Opacity Project data includes good predictions of atomic level energies and comparisons with large samples of oscillator strengths from other theoretical studies or laboratory measurements.

Line formation

Let us assume that the structure of the atmosphere (temperature, density, atomic level populations) is known, and let us examine first the limited problem of line formation. Why do most stellar spectra display *absorption* lines? What can we learn from *emission* line spectra?

We can recast equation (4) in the case of a semi-infinite atmosphere. The emergent intensity seen by an external observer ($\tau = 0$) at an angle θ to the normal of the surface ($\mu = \cos\theta$):

$$I_\nu(\tau = 0, \mu) = \int_0^\infty S_\nu(t_\nu)\, \mathrm{e}^{-t_\nu/\mu}\, \mathrm{d}t_\nu/\mu. \tag{6}$$

The emergent intensity is a weighted average of the source function along the line of sight. If we suppose further that the source function is a linear function of depth, $S_\nu(\tau_\nu) = S_{0\nu} + S_{1\nu}\,\tau_\nu$, then equation (6) yields:

$$I_\nu(\tau = 0, \mu) = S_{0\nu} + S_{1\nu}\,\mu = S_\nu(\tau_\nu = \mu) \tag{7}$$

which is known as the *Eddington–Barbier* relation. This result states that the emergent intensity is characteristic of the value of the source function at about optical depth unity along the line of sight. In a spectral line, we encounter optical depth unity in higher layers for frequencies with high opacity (line core) and in deeper layers for frequencies with low opacity (line wings, continuum). Therefore, emergent line profiles map the depth dependence of the source function. If we further assume LTE, $S_\nu = B_\nu$, the temperature structure can in principle be inferred. Absorption line stellar spectra indicate that the line source function decreases with increasing height in photospheres. In cool stars, line core emissions are observed in the strongest lines (e.g. Ca II H and K) showing that the source function increases in the highest layers. This has been straightforwardly interpreted as indicating a temperature decrease in the photosphere and a temperature rise in the upper layers (chromosphere). Recent hydrodynamical simulations suggest, however, that the real structure of the solar chromosphere may be more complicated; hot regions which are responsible for the line core emissions are embedded in a low-temperature, photosphere-like medium.

While the line profiles map the source function behavior, a straightforward interpretation in terms of temperature should be approached with caution. First, equation (6) shows that the source function at different depths contributes to the emergent intensity. Limiting the contribution to a single depth of formation is quite useful at first, but is still an oversimplification. The concept of *contribution functions* seems a preferable approach. Second, the source function contains a thermal term and a scattering term (equation (5)). While the mean intensity decreases with height as photons escape, the thermal term depends on the details of photoexcitations and recombinations. Therefore, an interpretation of the line profiles in terms of physical parameters requires a careful and detailed non-LTE analysis.

In extended atmospheres and in winds, line profiles provide additional information on the geometry and the dynamics of the atmosphere. The most typical signatures of stellar winds are asymmetric P Cygni line profiles.

Structural equations

A *model atmosphere* specifies all atmospheric state parameters as functions of depth (actually as discretized values along the depth coordinate because the problem is solved numerically). The list of parameters required to describe a model atmosphere depends on the basic assumptions of the model, but traditionally includes only electron temperature, total density electron density and atomic level populations. The detailed radiation field is generally not stored because it can be recalculated through a simple formal solution of the radiative transfer equation when all other state parameters are known. The

Dirac House, Temple Back, Bristol, BS1 6BE, UK

predicted emergent spectrum alone is sometimes stored separately, because this is the most interesting output to compare with observations.

The state parameters of a model atmosphere are most generally described by distribution functions, which are calculated by solving the kinetic equation. The set of equations to solve is in general truly enormous because the individual particles are not just the atoms and ions, but all excited states of atoms, ions and molecules. It is standard in kinetic theory to simplify this system by constructing equations for the moments of the distribution functions. After summation over all kinds of particles, one obtains the well-known hydrodynamic equations, namely the continuity equation, the momentum equation and the energy balance equation. In addition, particles of each type must satisfy a conservation equation. The moment equations form the set of equations that are actually solved. In full generality, this system remains still intractable, and some simplifying assumptions have to be made. Let us consider the classical model atmosphere: a one-dimensional, stationary and static medium. The system of equations simplifies to:

$$\left(\frac{\mathrm{D}n_i}{\mathrm{D}t}\right)_{\mathrm{coll}} = 0 \tag{8}$$

$$\mathrm{d}P/\mathrm{d}z = -\rho g \tag{9}$$

$$\nabla F_{\mathrm{rad}} = 0 \Longrightarrow F_{\mathrm{rad}} = \sigma T_{\mathrm{eff}}^4 \tag{10}$$

where $(\mathrm{D}n_i/\mathrm{D}t)_{\mathrm{coll}}$ is the collision term in the kinetic equation that describes creations and destructions of particles of type i, P is the total pressure, z the geometrical coordinate, ρ the total density, g the gravitational acceleration at the stellar surface, F_{rad} the radiative flux, σ the Stefan–Boltzmann constant and T_{eff} the effective temperature. These equations are called the *statistical equilibrium*, *hydrostatic equilibrium* and *radiative equilibrium* equations. The explicit form of the statistical equilibrium equation incorporates all individual radiative transitions (rates depend on $\bar{J}$) and collisional transitions (rates depend on T and n_e) that populate and depopulate every individual energy level i of all atoms and ions. Therefore, the basic structural equations must be solved simultaneously with the radiative transfer equation at a large number of frequencies to compute the radiative rates and the total radiative flux (equation (10)). While the structural equations depend on the radiation field, the absorption and emission coefficients appearing in the radiative transfer equations depend on the local temperature, density and populations n_i. All these equations therefore form a highly coupled, highly non-linear system of equations. It may be solved using linearization techniques and ALI schemes for radiative transfer.

The description of a plasma is greatly simplified if thermodynamic equilibrium holds. In this state, the particle velocity distribution (Maxwell distribution), the ionization (Saha formula) and the excitation (Boltzmann law) equilibria are specified uniquely by two thermodynamic variables, usually chosen as the absolute (electron) temperature T and the electron density (n_e). Because a stellar atmosphere is essentially a boundary, thermodynamic equilibrium cannot hold. As photons escape, there are energy and momentum losses that give rise to significant gradients in the state parameters. However, even if thermodynamic equilibrium cannot be assumed for the whole stellar atmosphere, we may still use the concept of *local thermodynamic equilibrium* (LTE). The Maxwell and Saha–Boltzmann distributions cannot be applied globally, but may be used locally for the local values of $T(\boldsymbol{r})$ and $n_e(\boldsymbol{r})$. On the other hand, the radiation field (which is by essence non-local) is allowed to depart from its equilibrium, Planckian, distribution. In non-LTE (NLTE) model atmospheres, some populations are allowed to depart from their LTE, Saha–Boltzmann distributions. A Maxwellian velocity distribution is still assumed to hold in most NLTE models.

Microscopically, LTE holds if all atomic processes are in detailed balance (i.e. the number of any given processes is balanced by the same number of opposite processes). Since electrons have a Maxwellian velocity distribution, collisions between atoms and electrons will distribute this temperature information among the atomic levels and will tend to maintain the local equilibrium. LTE is therefore a good approximation where collisions far outnumber radiative transitions. When radiative transitions dominate, LTE remains a good approximation as long as all radiative transitions are in detailed balance. This is verified in deep layers where a photon has a very low probability of escaping, but LTE will break down in upper layers. As photons escape, the number of photoexcitations will drop below spontaneous deexcitations, and the detailed balance requirement will not be met. Departures from LTE are thus most likely in hot stars (strong radiation field) and low-density atmospheres (supergiants). The validity of LTE is further discussed in the article on STELLAR ATMOSPHERES: EARLY-TYPE STARS.

The gray case

There is one further simplification that allows derivation of an analytical expression for the temperature structure: the gray case. Besides its historic importance, gray model atmospheres are the most obvious starting point for constructing more sophisticated model atmospheres. The opacity is assumed to be a constant, frequency-independent value. Usually, the Rosseland mean opacity is adopted:

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

$$\chi_\nu = \bar{\chi} = \chi_R = \frac{dB}{dT}\left(\int_0^\infty \frac{1}{\chi_\nu}\frac{dB_\nu}{dT}d\nu\right)^{-1}. \quad (11)$$

The Rosseland mean opacity is also used in modeling stellar interiors, because it yields the exact total radiative flux at depth using the diffusion approximation, and it will therefore give the correct temperature structure in the deepest layers of the atmosphere. The system of equations is greatly simplified by using frequency-averaged moments of the radiation field: J, the mean intensity, H, the flux, and K the second-order moment. The radiative equilibrium reduces to

$$J = B = \sigma T^4 \quad (12)$$

and the second moment of the radiative transfer equation:

$$\frac{dK}{d\tau} = H. \quad (13)$$

Invoking the Eddington approximation, $K = J/3$, which is a good approximation in the deep atmospheric layers where the radiation field is close to isotropic, one obtains

$$T^4 = \frac{3}{4}T_{\rm eff}^4\left(\tau + \frac{2}{3}\right). \quad (14)$$

A rigorous solution obtained by Chandrasekhar leads to a very similar temperature structure. The constant 2/3 is replaced by a slowly varying function of optical depth, the Hopf function $q(\tau)$, ranging from $q(0) = 0.577$ to $q(\infty) = 0.71$.

Non-gray LTE model atmospheres

Gray model atmospheres are not very useful when it comes to interpreting real stellar spectra. Spectroscopic analyses require construction of non-gray model atmospheres, solving the radiative transfer at a number of frequencies using the proper values of the absorption and emission coefficients. Constructing LTE model atmospheres requires a solution of the basic structural equations (e.g., equations (8)–(10)), where the statistical equilibrium equations are replaced by the Saha–Boltzmann equations. The absorption and emission coefficients are therefore functions of the local temperature and electron density. There is still a non-local coupling of the radiation field and matter properties via the radiative equilibrium equation that fixes the local temperature. The temperature structure is often derived via a temperature correction scheme, starting from the gray structure. The local density is derived by a direct quadrature of the hydrostatic equilibrium.

The numerical difficulty in LTE model atmospheres is the complex dependence of the absorption (and emission) coefficient on frequency. Heavy atoms and ions, like iron-peak elements, have millions of spectral lines, requiring solution of the radiative transfer for a huge number of frequencies. A statistical approach (frequency sampling) or a rearrangement of the absorption coefficient (opacity distribution functions, ODFs) must be used to reduce the number of equations to solve. The ODF technique is particularly efficient in LTE, because all opacity contributions from different sources can be grouped together (this is not possible when radiative transition rates are required to solve the statistical equilibrium equations). The combined effect of the opacity due to many spectral lines significantly steepens the temperature gradient in the atmosphere. This effect, known as *line blanketing*, may be explained qualitatively as follows. In the continuum-forming layers (where the continuum optical depth is about unity), photons are absorbed preferentially at frequencies corresponding to bound–bound transitions where the opacity is still large enough. The flux is blocked at these frequencies and thus has to increase at frequencies with low opacity so that the same total amount of energy is transported. This increase requires a steeper temperature gradient. The deepest and the shallowest layers are not affected by this effect (the optical depth is either very large or very small), thus implying that line opacity results in a higher temperature in the continuum-forming region. The cumulative effect of millions of lines alters the temperature structure of the atmosphere significantly and, therefore, line blanketing is an essential ingredient of model atmosphere construction (thus requiring complete and detailed opacities). Indeed, the change of the temperature gradient results in significant differences in the emergent spectrum.

Fully line-blanketed LTE model atmospheres calculated by Kurucz have become a standard. These model atmospheres incorporate the opacity of over 40 million atomic, ionic and molecular lines. Currently, these model atmospheres are available for a wide range of stellar parameters ($T_{\rm eff}$, log g, chemical composition) that characterize O-type to K-type stars of different metallicities. Spectral models of stellar populations make a broad use of Kurucz model atmospheres. LTE model atmospheres of very cool stars (M-type and cooler stars) have been constructed independently with several computer programs, designed by Gustafsson and co-workers, Tsuji, Johnson and co-workers, and Allard and Hauschildt. Complex molecular and dust chemistry occur in these cool atmospheres that are not included in Kurucz model atmospheres. The article on STELLAR ATMOSPHERES: COOL STARS provides additional discussion.

NLTE model atmospheres

Departures from LTE are expected when radiative rates dominate collisional rates, which typically occurs at high

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

temperatures and low densities. Therefore NLTE model atmospheres will be most important to interpret observations of hot stars (spectral types O, B and A), of extended atmospheres of supergiants and of stellar winds. Early, simple NLTE model atmospheres confirmed this trend. The Hertzsprung–Russell diagram was then roughly divided into two zones, one where LTE was deemed a good approximation, and another where non-LTE effects are important. However, in high-opacity regions like the extreme ultraviolet, the spectrum is formed very high in the atmosphere and thus is prone to non-LTE effects even in cooler stars. Moreover, this division of the HR diagram was based on a rough quantitative criterion. In the last 20 years, progress in observational techniques has resulted in spectroscopic data of much higher quality. The question of the necessity of non-LTE models should therefore be reconsidered in terms of the required accuracy in a given spectral range.

The construction of NLTE model atmospheres requires the solution of large systems of nonlinear equations. Iterative procedures based on the Λ iteration technique do not work due to the importance of the non-local coupling introduced by the radiation field. Upon this realization, Auer and Mihalas introduced the method of the complete linearization, in which all equations are treated on the same footing. This method requires inversion of matrices whose sizes are equal to the number of equations, and is therefore rapidly limited to a small number of atomic levels that are allowed to depart from LTE (generally, H, He and few CNO levels). These early NLTE model atmospheres confirmed that LTE is an inadequate assumption for modeling hot stellar atmospheres. During the same period, however, the importance of line blanketing was stressed. It was then quite unclear which of the simple NLTE models or LTE line-blanketed models had to be preferred to model hot stars. The emergence of the ALI methods broke the limitations of the complete linearization method and led to more sophisticated NLTE model atmospheres. In recent years, NLTE line-blanketed model atmospheres incorporating fully consistent non-LTE iron-peak element opacity have been constructed. Extensive grids like the Kurucz LTE grid of model atmospheres still do not exist, but are expected to become available in the near future.

Early NLTE wind models also were relatively simple, including only a few non-LTE atomic levels, a simple photosphere as a boundary condition and using the Sobolev approximation throughout the wind. Here again, the ALI methods allowed the incorporation of more species with more detailed model atoms, including also the effect of iron-line blanketing, at least in a statistical sense. The energy balance and the momentum equations are not solved in most wind models, but an empirical temperature and velocity structure of the wind is assumed. The temperature often follows a gray structure, while the velocity is given as a simple parametric law (β-type law). In the last decade, a group at Munich University led by Kudritzki has put a tremendous effort into constructing so-called *unified model atmospheres*. Unified models treat the photosphere and the wind on the same footing, and they solve the energy balance and the momentum equations assuming a parameterized force due to line radiation pressure. Further discussion of NLTE wind models may be found in the article on RADIATIVELY DRIVEN STELLAR WINDS FROM HOT STARS.

Non-thermal phenomena

Thanks to the significant advances in x-ray instrumentation during the last 20 years, it has become clear that x-ray emission is widely present in stars of different spectral types. This emission indicates the presence of hot, coronal, million-degree material. From pressure and radiative equilibria, this implies that the emitting regions have very low densities, are very high in the atmosphere and are heated by non-radiative energy deposition in these layers.

The main properties of stellar x-ray emissions can be summarized as follows:

- Essentially all cool main-sequence stars of spectral types F to M are x-ray emitters, with x-ray luminosity in the range $10^{26–31}$ erg s^{-1}. The full range of x-ray luminosity is observed within all spectral types, and the average luminosity is nearly independent of spectral type.
- O- and B-type stars have an x-ray luminosity, L_X, in the range $10^{29–34}$ erg s^{-1}. The x-ray luminosity is approximatively proportional to the bolometric luminosity, $L_X/L_{bol} \approx 10^{-6}$. It is also correlated to the momentum flux in the wind or, alternatively, to the wind kinetic energy flux.
- Main-sequence stars in the spectral range B8 to A5 are not detected, with the exception of some magnetic Ap stars.
- X-ray emission in cool giants and supergiants shows a cut-off in emission level corresponding to a transition between strong winds and coronal emission.

The observed relation between the x-ray luminosity and the wind properties of early-type stars indicates that x-rays are emitted in fast, massive radiatively driven winds. Instabilities in the wind lead to the formation of shocks and to the associated non-thermal radiative emission. This mechanism cannot, however, explain the x-ray emission of later-type stars, because the predicted luminosity would fall far short of the observations due to the steep decrease of the total luminosity.

The first standard models of the solar corona heating were based on energy deposition by acoustic waves.

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Based on this mechanism, it was expected that the Sun would be close to the top of the distribution of stellar x-ray luminosities. Moreover, the amount of energy carried by the outer convective envelope that could be transported by acoustic waves decreases rapidly towards later spectral types. However, x-ray surveys did not reveal such a decrease of the x-ray luminosity towards later spectral types, and the solar x-ray luminosity is rather below average. Acoustic waves are therefore not the source of coronal heating. They are, however, the most likely source of *chromospheric* heating. Observations recorded with the Solar Heliospheric Observatory (SOHO) are showing that acoustic waves are damped in the upper chromosphere and do not propagate through the transition region.

While the level of coronal emission does not correlate with spectral type, a clear correlation with the rotation rate has been established. Moreover, the solar data indicate a connection between activity and magnetic field strength. The magnetic field is generated by a *magnetic dynamo* with an efficiency depending on the rotation period of the star. By themselves, rotation or magnetic fields do not result in coronal emission. Detailed solar models indicate that magnetic fields must be embedded in a strong convective pattern in order for mechanical energy to be transported to and deposited in the upper atmosphere. With the disappearance of the outer convective zone in stars with spectral types earlier than A7, this heating mechanism vanishes. Indeed, no coronas or related x-rays are observed in early-type stars. At the other end of the spectral sequence, stars are becoming completely convective at spectral type M5. The dynamo efficiency and related emission might thus decrease in stars later than M5. Finally, activity is decreasing with age too: the weak solar-like wind of cool stars carries away angular momentum and spins down these stars on timescales of the order of 10^9 years.

Despite this general understanding, the physics of the outer atmosphere of solar-like stars is still poorly understood. High spatial resolution images of the Sun in the x-ray and extreme ultraviolet domains reveal the complex structure of the solar upper atmosphere. Active cool stars reveal similar complexity with large spots on their surface. The simultaneous study of the Sun and late-type stars (the so-called solar–stellar connection) has so far been quite fruitful and will remain an essential avenue towards a better understanding of late-type stars and non-thermal phenomena in stellar atmospheres.

Future developments

Progress and success in NLTE modeling of stellar atmospheres and winds has been tremendous during the last three decades. Now it remains to make NLTE models as common as the very successful LTE model atmospheres constructed by Kurucz. This step is essential to benefit from the improved physics of NLTE model atmospheres in analyzing the huge number of spectra that will be recorded by the new generations of large telescopes and multiaperture spectrometers. In this respect, the availability of grids of NLTE line-blanketed model atmospheres is a necessary step. Such grids of models will be particularly important for stellar population studies too. On the other hand, progress in including iron-line blanketing and consistently solving the momentum and energy balance equations in unified model atmospheres should be very rewarding in the analysis of the spectra of the brightest individual objects in external galaxies as far as the Virgo cluster. Unified model atmospheres should put the spectral analysis of these objects on the best physical footing to derive the surface chemical composition and the mass loss rate of these objects; prime quantities to understand the effect of stellar evolution on the evolution of galaxies. Most importantly, such analyses will provide an independent method of deriving the stellar distances of these distant objects. In cool stars (including brown dwarfs and giant planet atmospheres), future emphasis will be given on improving molecular and dust chemistry, in particular in the presence of shocks. The opacity and thus the emergent spectrum can be altered significantly by changing the molecular equilibria and by the formation of dust.

While considerable progress remains to be made in 1D model atmospheres, we may expect that more and more attention will be devoted to multidimensional geometries. The methodology for solving radiative transfer in 2D or 3D is well known. The fastest method is based on the short characteristics method (integration of the formal solution between any two spatial grid points). However, the number of directions in which the radiative transfer must be solved to compute angle-averaged quantities like the mean intensity increases dramatically to obtain a good accuracy (typically by up to two orders of magnitude). This is especially true when the radiation field is strongly peaked or in the presence of strong gradients, because the photons can escape much more easily in one direction than in others. The additional spatial dimension(s) in the model could therefore alter significantly the structure of the model and the predicted emergent spectrum. The requirement to solve the transfer equation in many directions results, however, in very demanding computer simulations, even for a simple description of the plasma including very few NLTE atomic levels. Examples of astrophysical objects requiring multidimensional simulations and currently under investigation include models of rotating winds, of colliding winds, of circumstellar disks, of solar prominences and other structures in the solar atmosphere. Multidimensional radiation hydrodynamics is a field in its infancy that is now developing thanks to the available computing power.

Web update

For the first time, an optical coronal line from a star other than the Sun has been detected. The UV-Visual Echelle Spectrograph (UVES) on the VLT 8.2 m KUEYEN telescope at the ESO Paranal Observatory has observed a coronal emission line in nearby variable star CN Leonis from iron ions that have lost 12 electrons (Fe XIII). CN Leonis, a cool star, is located at a distance of 8 light-years.

Bibliography

The fundamental textbook of the field is:

Mihalas D 1978 *Stellar Atmospheres* 2nd edn (San Francisco: Freeman)

Theoretical and observational aspects of the stellar atmospheres are both covered in a good textbook and some lecture notes from a recent European Astrophysics School:

Stellar Atmospheres: Cool Stars

The term 'cool stellar atmosphere' is generally applied to the atmospheres of stars with effective temperatures less than that of the Sun. In this spirit, this article describes the basic physics of stellar and substellar atmospheres with effective temperatures below about 5000 K. This category includes two common subclasses: dwarf stars and giant stars. From the point of view of the STELLAR ATMOSPHERE, the main difference between these subclasses is a question of geometry: plane parallel geometry for dwarfs and spherical symmetry for giants. The types of stars that fall in the 'cool' category reach from evolved M giants and AGB stars to M dwarfs and the new spectral class 'L' proposed for extremely low-mass dwarf stars and brown dwarfs. Although these objects have very different astrophysical origin and history, their atmospheres are described by the same equations and input physics.

Model atmospheres for cool stars are used not only to determine stellar parameters such as effective temperatures and elemental abundances but also as input data for STELLAR EVOLUTION models (very low-mass stars) and population synthesis modeling. Thus the accuracy and quality of our understanding of cool stellar atmospheres has far-reaching impact on other fields of astrophysics.

Cool stellar atmospheres are extraordinarily complex, which makes them hard to understand and model. The main reasons for this are

1. the importance of molecules for the chemical equilibrium and the radiative transfer,
2. the extraordinary importance of spectral line opacities and line broadening,
3. convective energy transport into the outer optically thin regions of cool dwarf atmospheres,
4. formation of dust for very low effective temperatures ($\lesssim$ 2500 K),
5. deviations from local thermodynamic equilibrium (LTE) and local chemical equilibrium.

Further complications can include for example STELLAR PULSATIONS and winds in giant stars or fast rotation and chromospheric activity in young dwarf stars. The following sections will concentrate on the most important problems.

Basic physical picture

In the classical approach a cool stellar atmosphere is assumed to be in time-independent hydrostatic equilibrium. The atmospheres can furthermore be described by using either plane parallel geometry for dwarf stars with gravities $\log(g) \gtrsim 3.5$ or spherical geometry for giant stars with lower gravities.

The luminosity L of the star is parameterized through the effective temperature $T_{\rm eff}$ via

$$L = \sigma T_{\rm eff}^4 4\pi R^2$$

where σ is the Stefan–Boltzmann constant and R is the radius of the star. The pressure structure of the atmosphere in spherical geometry is given by

$$\frac{\mathrm{d}P}{\mathrm{d}r} = -g(r)\rho(r)$$

where the total pressure P is the sum of the gas pressure $P_{\rm gas}$ and the radiation pressure $P_{\rm rad}$ (in some cases an additional turbulent pressure term has to be considered), r is the distance from the center of the star and

$$g(r) = \frac{GM}{r^2}$$

is the gravity where G is the gravitational constant and M is the mass of the star. For dwarf stars with a negligible radial extension of the atmosphere ($\Delta r/R \ll R$) the gravity can be set constant and used as one parameter of the atmosphere.

The energy generated in the deep interior of the star is transported through the atmosphere predominantly by radiation and by convection so that

$$L = L_{\rm rad}(r) + L_{\rm conv}(r) = \text{const}$$

where $L_{\rm rad}(r)$ is the luminosity carried by photons and $L_{\rm conv}(r)$ is the convective luminosity. Cool atmospheres typically have an outer radiative zone where $L_{\rm conv} = 0$ and an inner convective zone where $L \approx L_{\rm conv}$. In very low mass dwarf stars ($M \lesssim 0.5 M_{\rm Sun}$) the convective region reaches out into the optically thin regions of the atmosphere and from there up to the center of the star, leaving only a thin outer radiative layer ('fully convective stars'). There is currently no detailed analytical or quantitative theory of convective energy transport and thus parameterized approaches are generally used in the context of detailed stellar atmosphere models. The most common approach is the mixing length theory with a single free parameter ℓ, called the mixing length (typically 0.5–1.5 times the local pressure scale height of the atmosphere). The convection in cool dwarf atmospheres (M dwarfs and later) is extremely efficient and becomes practically adiabatic; this removes partly the ambiguity of the mixing length parameter for these stars.

In order to calculate the radiative luminosity

$$L_{\rm rad}(r) = 4\pi r^2 \int_0^\infty F_\lambda(r,\lambda)\,\mathrm{d}\lambda$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the radiation flux F_λ (r,λ) must be known at all wavelengths λ. For the cases of plane parallel and spherical geometry F_λ is given by

$$F_\lambda = 2\pi \int_{-1}^{1} I_\lambda(r, \lambda, \mu)\mu \, \mathrm{d}\mu$$

where μ = cos(θ) and θ is the angle of a beam of radiation with the specific intensity $I_\lambda(r,\lambda,\mu)$ to the radially outward direction. The specific intensities $I = I_\lambda(r,\lambda,\mu)$ are obtained from the solution of the radiative transfer equation, which is given for the general case of a special relativistic flow in spherical symmetry by

$$e\frac{\partial I}{\partial r} + \frac{\partial}{\partial \mu}(f I) + g\frac{\partial}{\partial \lambda}(\lambda I) + hI = \eta - \chi I$$

with

$$\beta(r) = \frac{v(r)}{c}$$

$$\gamma^2 = 1/(1-\beta^2)$$

$$e(r,\mu) = \gamma(\mu + \beta)$$

$$f(r,\mu) = \gamma(1-\mu^2)\left[\frac{1+\beta\mu}{r} - \gamma^2(\mu+\beta)\frac{\partial\beta}{\partial r}\right]$$

$$g(r,\mu) = \gamma\left[\frac{\beta(1-\mu^2)}{r} + \gamma^2\mu(\mu+\beta)\frac{\partial\beta}{\partial r}\right]$$

$$h(r,\mu) = \gamma\left[\frac{\beta(1-\mu^2)}{r} + \gamma^2(1+\mu^2+2\beta\mu)\frac{\partial\beta}{\partial r}\right]$$

where $v(r)$ is the flow velocity. For static atmospheres, $v(r) = 0$, and for static plane parallel atmospheres one has in addition $f(r,\mu) = 0$. To solve the radiative transfer equation, the emissivities $\eta = \eta_\lambda(r,\lambda)$ and the extinction $\kappa = \kappa(r,\lambda) + \sigma(r,\lambda)$ coefficients must be known. Here, $\kappa(r,\lambda)$ is the total absorption coefficient and $\sigma(r,\lambda)$ is the total extinction coefficient. For simple isotropic scattering the emissivity η can be written in the form

$$\eta(r,\lambda) = \kappa(r,\lambda)B_\lambda(\lambda, T) + \sigma(r,\lambda)J_\lambda(r,\lambda)$$

where $J(r,\lambda)$ is the mean intensity. The first term describes the thermal sources present in the atmosphere whereas the second term describes scattering. Thus, in order to calculate the radiation field inside the atmosphere, κ and σ must be known. This requires the detailed knowledge of the partial pressures of each atom, ion and molecule present in the atmosphere through a solution of the equation of state (EOS) for cool atmospheres as well as the detailed knowledge of the interaction of each species with radiation through, e.g., photoionization and spectral lines.

Equation of state

The EOS describes the distribution of the available nuclei in a volume element (say, 1 cm^3) to atoms, ions and molecules. Within the atmosphere, the EOS is usually assumed to be that of an ideal gas. This assumption is justified for all but the deep layers of very cool atmospheres where non-ideal gas effects become important. In addition, the assumptions of local chemical equilibrium and LTE are typically made in order to simplify the calculation of the concentrations of individual species (atoms, ions and molecules). The low temperatures in cool atmospheres lead to the formation of a large number of different molecules, which makes their EOS extremely complex. Although there are only a few molecules with large concentrations, such as molecular hydrogen H_2, carbon monoxide (CO), titanium oxide (TiO) and water vapor (H_2O), there are many more molecules with smaller concentrations. These cannot be neglected, however, because their spectral lines can be very strong and thus significant for the energy transport in the atmosphere. Some examples of these important trace molecules are vanadium oxide (VO) and metal hydrides such as MgH, CaH and FeH. The concentrations of these molecules are low but they have important bands of spectral lines that dominate the emitted spectrum at certain optical and red wavelengths. In addition to the important opacity sources, many more molecular species with trace concentrations have to be included because the dependences of the formation and dissociation of all molecules as well as the concentrations of atoms are highly non-linear and even small changes in the concentration of trace species can have significant effects on molecules with important spectral lines. Therefore, the EOS typically includes several 100 molecular species in addition to a number of atoms and ions.

In very cool atmospheres with effective temperatures below about 2500 K the formation of dust grains becomes important and has to be considered in the EOS. This is shown in figure 1 which shows the species with the highest concentrations for both the gas and the condensed phases for a model atmosphere with T_{eff} = 1000 K under the assumption that no settling of the dust particles took place. The figure shows for example that iron condenses from the gas phase (labeled 'Fe') to the solid phase (labels 'Fe/c' and 'Fe/c1' for different condensate forms) around an optical depth of 1. High-temperature condensates such as Al_2O_3 and $CaTiO_3$ form in small concentrations but can have a significant impact on the total opacity of the atmosphere. At lower temperatures condensates such as Fe_3O_4 and water ice form. The main thermodynamic effect of grain formation is to remove the condensed elements from the gas phase, thus changing the concentration of the complete set of molecules. This reduces the opacity of important molecules such as TiO. In addition, the condensates

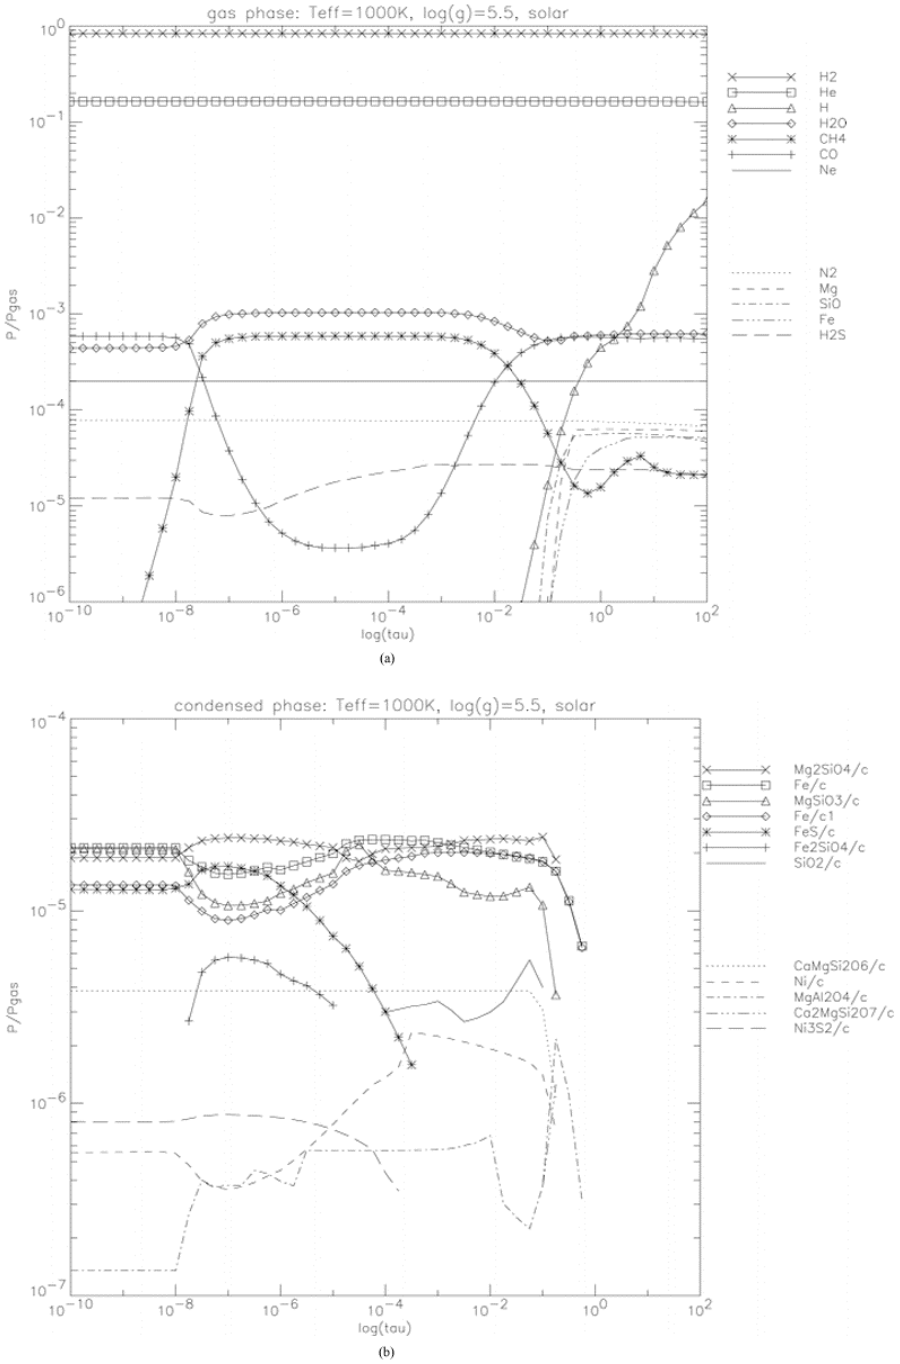

Figure 1. The most important (by concentration) gas phase and condensed phase species in a cool atmosphere with an effective temperature of 1000 K, a gravity of $10^{5.5}$ cm s^{-2} and solar abundances (roughly equivalent to the parameters of the brown dwarf Gl 229B). The *x*-axis gives the optical depth in the continuum at 1.2 μm, the *y*-axis gives the relative concentration.

themselves have an effect on the opacity and thus the structure of the atmosphere; see below.

The molecular EOS is a coupled non-linear system of equations even in the simplest case of complete local chemical equilibrium and LTE. This system can in principle be solved by any appropriate numerical technique, e.g. Newton's method or free energy minimization algorithms. The assumption of local chemical equilibrium and LTE is not always a good approximation. For example, the process of dust formation in cool giant atmospheres is not well understood and deviations from local chemical equilibrium are likely important.

Opacities

Atomic opacities

The opacities in cool stellar atmosphere are dominated by spectral lines of molecules. Atomic processes are important mostly through individual spectral lines that are useful as diagnostics of the structure of the atmosphere and as abundance indicators for individual elements; however, most of the line blanketing is provided by molecular spectral lines. Atomic photoionization and recombination processes lose their importance toward lower effective temperatures and are completely dominated by spectral line absorption and emission. At low temperatures, when molecules form and condensation begins, the strengths of some atomic lines are gradually reduced as the elements are either tied up in molecules (with their own, different set of spectral lines) or as they condense into grain particles (which become important opacity sources themselves). At the same time, however, the atmosphere becomes more transparent in certain wavelength regions which leads to an increase in the strength of other spectral lines. In giants these depletion processes are reduced owing to the lower pressures in the atmospheres so that atomic lines are relatively more important for a cool giant atmosphere than in a cool dwarf atmosphere with comparable effective temperature. The number of atomic lines important in cool atmospheres also drops quickly as the effective temperature drops because exited levels are less and less populated at lower gas temperatures. The strong line blanketing by millions of spectral lines from atoms and ions (e.g. singly ionized iron, Fe II) typical for hotter atmospheres has been reduced to only a few remaining resonance lines (originating from the ground state) of atoms. See also STELLAR OPACITY.

Only the strongest resonance lines of alkali metals remain observable in very cool atmospheres: important atomic lines are the Na I-D lines at λ 5889, 5896 Å, Na I lines at λ 8183, 8195 Å and λ 10 746, 10 749, 10 835 Å and at 2.2 μm, K I at λ 6911, 6939, λ 7665, 7699, λ 9950, 9954 and λ 10 480, 10 482, 10 487 Å. Resonance lines of Rb I at λ 7950 Å, and Ba I at λ 7911, 7913 Å are also particularly strong in very cool dwarf atmospheres and Cs I λ 8521, λ 8944 Å lines appear strong in class 'L' dwarfs. The resonance lines of neutral lithium between 6708 and 6710 Å are important indicators of the substellar nature of cool dwarfs because lithium is destroyed by thermonuclear reactions in stars. Only objects below the hydrogen burning limit will conserve their initial lithium abundance.

Atomic lines in cool atmospheres are very broad owing to van der Waals (vdW) interaction of the parent atom with neutral particles in the gas (mostly He and H_2). This effect perturbs the energy levels of the atoms leading to strong vdW broadening of atomic lines in cool atmospheres. The vdW broadening leads to a Lorentzian line profile with form

$$\phi(\Delta\lambda) = \frac{\Delta\lambda_L}{2\pi}\frac{1}{\Delta\lambda^2 + \Delta\lambda_L^2/4}.$$

The vdW linewidth can be written in the form

$$\Delta\lambda_L = \frac{\lambda_0^2}{2\pi c}\gamma_{vdW}$$

with the vdW damping constant

$$\gamma_{vdW} \propto C_6^{2/5} v^{3/5} N_p$$

where v is the relative speed between the absorbing–emitting particle and the perturber and N_p is the number density of the perturbers. The interaction constant C_6 can be calculated with reasonable accuracy only for fast (compared with the lifetime of the transition) perturbations with neutral hydrogen. However, in cool atmosphere the most important perturbers are molecular hydrogen and helium and the perturbations relatively slow. For these cases, no general quantitative theory exists and approximations are generally used, such as Unsöld's modified hydrogenic approximation of the form

$$C_6 = 1.01 \times 10^{-32}(Z+1)^2\left[\frac{E_H^2}{(E-E_l)^2} - \frac{E_H^2}{(E-E_u)^2}\right]$$

where Z is the charge of the absorber, E the ionization energy, E_l and E_u are the lower and upper level excitation energies of the absorber and the result has the units cm^6 s^{-1}. This approximation works reasonably well for alkali metals but for other elements correction factors ranging from 10 to ~65 had to be introduced to provide reasonable results.

Molecular bands

Figure 2 gives an overview over the most important opacity sources present in the atmosphere of a dwarf star with an effective temperature of 2800 K and solar elemental abundances. The figure clearly shows the overall importance of TiO and water vapor lines in the optical and near-infrared (NIR) spectral regions, respectively. The number of spectral lines per molecule is *vastly* greater than for atoms or ions. For example, modern line lists include about ~175 million lines of TiO and ~300 million lines of water vapor. The spectral lines of molecules are clustered in molecular bands. This has led early on to the development of approximate treatments of molecular opacities by methods such as the just overlapping line approximation (JOLA) or simple straight means techniques. These methods assume that

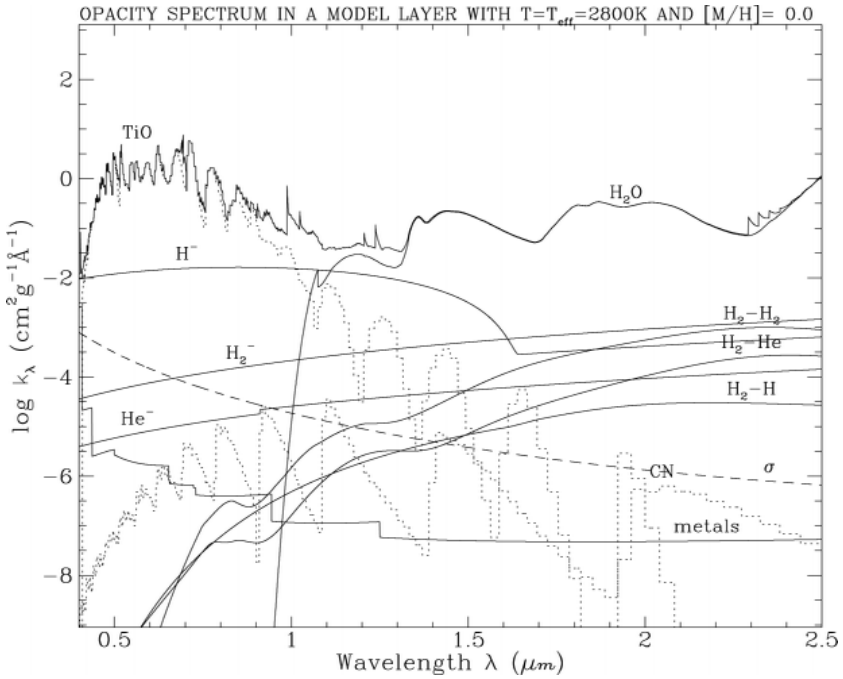

Figure 2. Most important absorbers in a cool stellar atmosphere with an effective temperature of 2800 K, a gravity of 10^5 cm s^{-2} and solar abundances of all elements. This graph does not include the effects of dust settling observed in very cool atmospheres. From Allard F and Hauschildt P H 1995 *Astrophys. J.* **445** 433.

the fine structure of the molecular bands is completely smeared out and that the lines overlap without being saturated. This tends to overestimate the molecular line blanketing by preventing photons from escaping through narrow gaps between molecular lines, resulting in significantly higher temperatures in the atmosphere as compared with the temperature structure obtained with detailed treatment of the individual molecular lines. However, detailed and complete line lists exist only for a limited number of molecules; for many important molecular absorbers only approximate treatments based on the JOLA are available (and even then many times only with estimated band strengths). This is currently the case for such important molecular absorbers as VO, FeH and CaH.

The most important molecular bands in the optical spectral region are TiO and VO for stars with SOLAR ABUNDANCES. For stars with metallicities less than solar, hydrides such as FeH (stars later than M6), MgH, and CaH become important opacity sources, partly because of reduced TiO opacity at lower metallicities. A number of molecules have individual bands that can be important in localized wavelength ranges, e.g. MgH, SiH, OH, CaOH (among the strongest band systems in cool M dwarf stars) and CH. TiO and VO are often used as temperature indicators owing to the sensitivity of the lines to the temperature structure of the atmosphere. The hydride lines appear stronger with increasing gravity, thus making these bands useful as gravity indicators. In low-gravity carbon-enriched atmospheres, species such as CN, ZrO, LaO (S stars) and YO can show important bands in individual wavelength ranges. Although none of these trace molecules contributes significantly to the overall line blanketing in normal cool stars (which is provided mostly by TiO, VO and H_2O) they do absorb in optical spectral regions where TiO is relatively weak and they thus provide local traps for photons trying to escape from the atmosphere.

The NIR and infrared (IR) spectral range in cool dwarf stars with solar abundances is dominated by the opacity of water vapor, which is typically 1–2 orders of magnitude stronger than the next closest opacity sources in this spectral region. The exceptions are the first overtone band of CO between ~2.3 and ~2.4 μm which is very prominent in cool stellar atmospheres and the CO fundamental band at ~4.5 μm, making CO a good temperature indicator in the IR. One of the biggest current challenges in modeling cool stellar atmospheres is to obtain better line lists for water vapor. The problem is the complexity of calculating accurate line positions and strengths for a triatomic molecule such as water at the relatively high (compared with Earth standards) temperatures in the atmospheres of cool stars. This actually means that the water opacity problem is larger for higher effective temperatures, as the low-temperature lines of water vapor are generally better known. Similarly, better line data for VO and methane are also urgently needed.

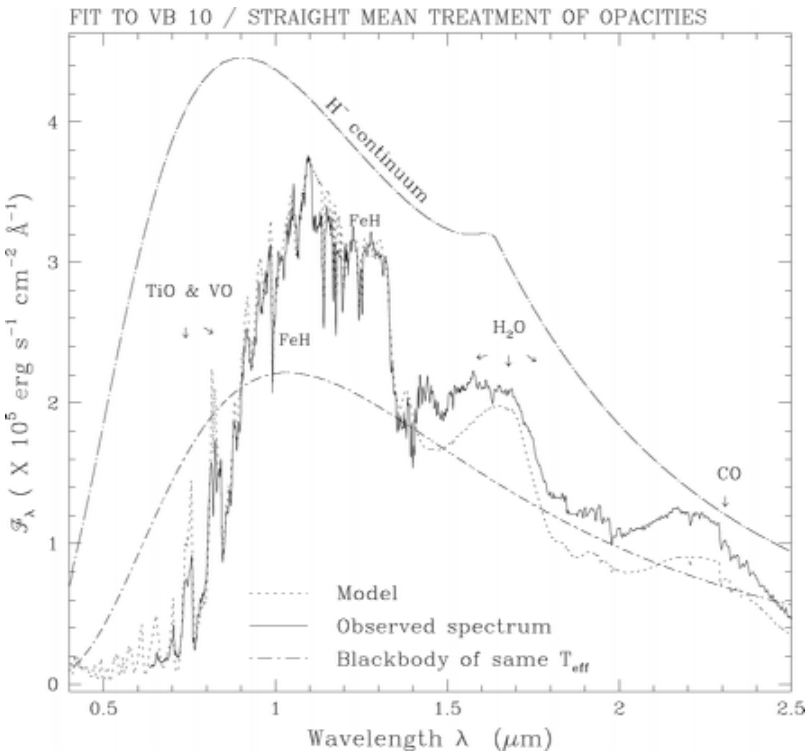

Figure 3. Illustration of the importance of molecular spectral line opacities of cool stellar atmospheres. The plot shows the spectrum of the star VB10 compared with a simple model. The molecular species with the strongest features are indicated. For comparison, a blackbody spectrum with the same effective temperature and the run of the H^- continuum are also given. From Allard F and Hauschildt P H 1995 *Astrophys. J.* **445** 433.

The large number of molecular spectral lines makes the classical notion of the 'continuum' basically useless for cool stellar atmospheres. This is demonstrated in figure 3 for a dwarf star synthetic spectrum with an effective temperature of 2800 K (for comparison, the observed spectrum of the star VB10 is also shown). The curve labeled 'H^- continuum' shows the spectrum calculated by omitting all molecular opacities and retaining only the opacity of the negative hydrogen ion H^-. This shows clearly the importance of the molecular lines in the overall energy distribution of cool stars. In addition, figure 3 shows how much the spectra emitted by cool stellar atmospheres deviate from the blackbody energy distribution (shown as dot-dashed curve) for the same effective temperature. The strong overlap between molecular lines actually helps to reduce the problem of the largely unknown damping constants for molecular lines by effectively masking the details of the line wings.

Dust opacities

The opacity of dust particles becomes important in very cool dwarf stars or in the outermost atmospheres of cool giant stars. Once condensates start to form, the opacity due to the grains can dominate the formation of the spectrum. The opacity of dust particles follows from the Mie theory for given shape, size and optical properties of the particles. Two important differences from the other opacity sources discussed above are (1) dust particles cause a significant amount of non-isotropic photon scattering in cool atmospheres and (2) they have very broad features that affect nearly the whole spectrum. For example, dust grains tend to very effectively absorb photons in the optical spectral range. The absorbed energy is thermalized and re-emitted in the IR range. This leads to a strong re-processing of photons from the optical to the IR and to a heating of the atmosphere.

The presence of dust particles increases the number of parameters of the atmosphere significantly as the size and shapes of the grains must be known. In principle, this could be calculated using a non-equilibrium model for the formation and growth of the dust particles, but this is currently not feasible within the simulation of a cool atmosphere itself. Thus statistical approximations are used and suitable averages over grain size and shape distributions are made. In addition, the optical parameters of each dust species have to be known, e.g. from databases. Some of the important dust opacity sources include species such as $MgSiO_3$, Mg_2SiO_4, soot, FeS, condensed metals (e.g. Fe, Cu, Ti), Al_2O_3 (corundum and sapphire), Fe_2O_3, Fe_3O_4, water ice, ZrO_2, $CaTiO_3$, $MgAl_2O_4$, $CaSiO_3$ and other calcium silicates. For many

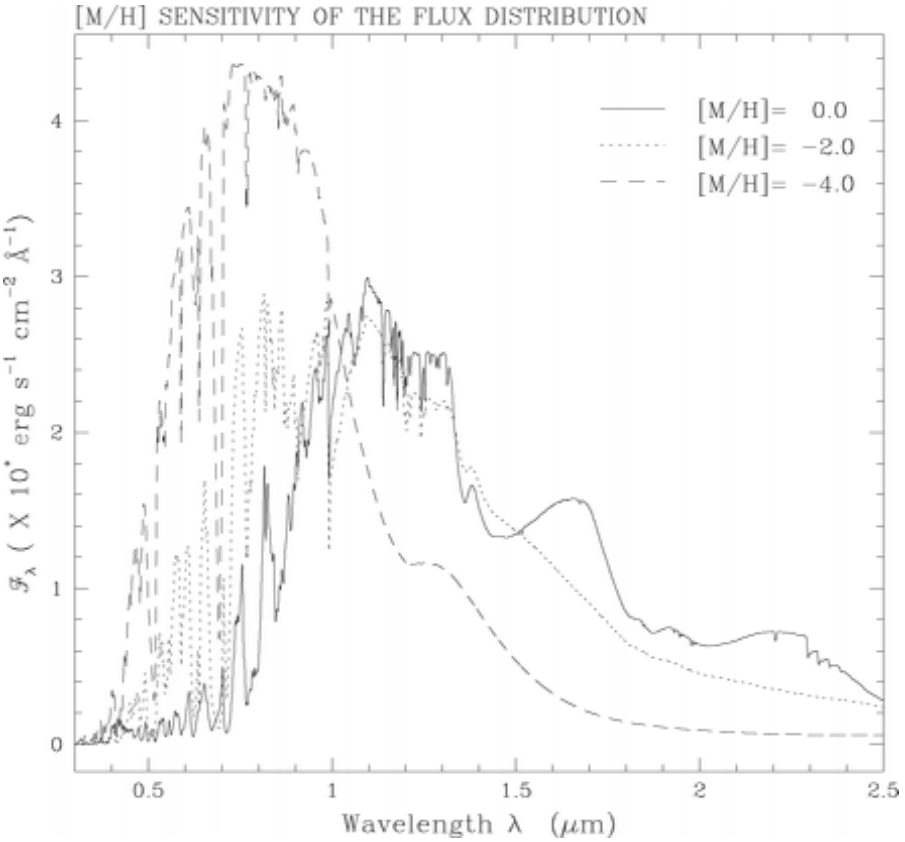

Figure 4. Low-resolution synthetic spectra for cool atmospheres of different metallicities corresponding roughly to the young disk ([M/H] = 0.0), halo ([M/H] = –2.0) and population III ([M/H] = –4.0). The effective temperature is 2800 K and the gravity is log *g* = 5.0 for all models. From Allard F and Hauschildt P H 1995 *Astrophys. J.* **445** 433.

of the important species the optical properties are either not or only poorly known.

A further complication is the apparent settling of dust particles in the coolest known brown dwarf atmospheres. The IR spectra of these objects indicate less dust opacity than expected from condensation models. This is corroborated by the presence of stronger atomic lines than predicted by condensation models. However, the relatively weak water vapor bands indicate the presence of dust in the layers where the water bands form. The current model for this effect is that the dust particles have partially settled below the photosphere. This delivers the desired effect and results in improved fits to observed brown dwarf spectra. For objects with effective temperatures above about 2000 K the dust does not seem to settle and the best results are achieved using full dust opacities. The reason for this might be the fact that the convection zone reaches far into the outer atmosphere for temperatures above 2000 K but retracts from the surface for cooler models. The convection zone could provide the mixing and turbulent motions required to prevent the settling of the dust particles and/or replenish the photospheric layers with refractory material. However, within the framework of the mixing length theory it appears that the convection zone never reaches into the layers of dusty atmospheres where the spectrum forms. This suggests that other mechanisms such as fast rotation or acoustic waves generated by the convection zone might be important.

NLTE effects

Because of the very low temperatures of cool stellar atmospheres, the electron density is extremely low. Collisions with particles other than electrons, e.g. H_2 or helium, are not as effective as electron collisions in restoring LTE, because both of their smaller cross-sections and their much smaller thermal velocities. Therefore, collisional rates which tend to restore LTE tend to be very small in cool stars. This in turn could significantly increase the importance of non-LTE (NLTE) effects in cool atmospheres (with effective temperatures below about 4000 K) when compared with, e.g., solar-type stars with much higher electron densities and temperatures. Departures from LTE in the photospheres of cool stars have been investigated in detail in the line transfer and dissociative equilibrium of H_2 in RED GIANT atmospheres and NLTE effects of CO

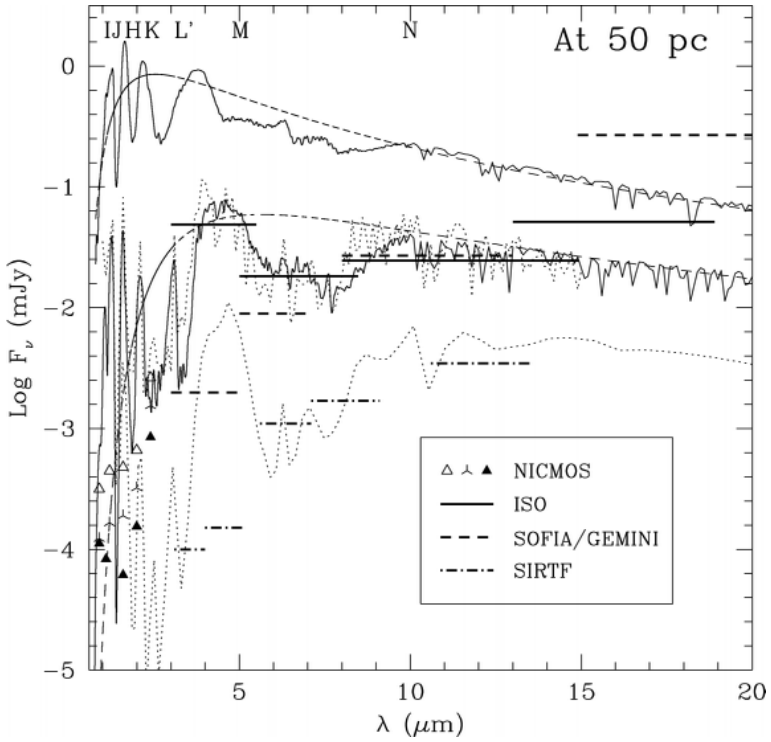

Figure 5. Examples of calculated energy distributions from very cool atmospheres, from the top to the bottom: 2000 K, ~1000 K and 500 K. The letters indicate the location of important broad-band filters. Detection limits for objects of the indicated effective temperature at a distance of 50 pc are given for some space- and ground-based telescopes. From Allard F *et al* 1997 *Ann. Rev. Astron. Astrophys*. **35** 137.

have been investigated both in the Sun and in red giant atmospheres. These studies led to the conclusion that even after the passage of pulsationally driven shocks the recombination of H_2 and CO must proceed rapidly, leading to number densities very close to LTE values. However, in cool atmospheres it has been shown that the equivalent widths of the Li I and Na I resonance lines are affected by NLTE effects and NLTE curves of growth have been derived for a range of model parameters. Departures from LTE of the Ti I atom, and thus indirect changes in the concentration of the important TiO molecule, could therefore have severe and measurable consequences for the atmospheric structure and spectra of cool stars. However, although the NLTE effects in Ti I are noticeable they do not affect the formation of the TiO molecule and its opacity.

One of the open problems is a better understanding of the effects of NLTE on the formation, dissociation and line formation of important molecular species (CO, TiO and H_2O) in cool atmospheres. The main issues are the availability of data, in particular collisional cross-sections, and the technical problems due to the extremely large number of energy levels and spectral lines found in even simple molecules. The latter problem can be addressed by using modern numerical methods such as the operator splitting approach. The data problem, however, is still a major obstacle for detailed NLTE calculations for molecules.

Spectra

The richness of the spectrum emitted by a cool stellar atmosphere is apparent in figure 3. The identification of individual spectral lines is only possible for the strongest resonance lines of atoms. For molecules, only broad features can be identified. The spectrum shown is typical for dwarf stars in this effective temperature range. The peak of the energy distribution is locked at a wavelength ~1.1 μm by the combined effects of TiO lines in the optical and water vapor lines in the IR. Lowering the temperature, which shifts the peak of the corresponding blackbody energy distribution toward larger wavelengths, increases both the TiO and the H_2O opacities rapidly. This leaves only a few small windows open in the 1–2 μm range through which the atmosphere can radiate its thermal energy. Therefore, the location of the peak of the energy distribution of cool dwarf stars is not a good temperature indicator. The slope of the spectrum in this wavelength interval is a more useful temperature indicator. This situation is changed only when dust opacity starts to become important in the optical spectral range at lower effective temperatures.

A similar effect leads to an unexpected behavior of the emitted spectra for a given effective temperature as a

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

function of metallicity as illustrated in figure 4. For lower metallicities, the opacities of both TiO and water vapor are reduced owing to the smaller concentration of the molecules. At the same time, collision-induced opacities due to H_2–H_2 and H_2–He become very strong in the IR and thus block the escape of photons. The trapped energy is then emitted in the optical spectral range, thus making low-metallicity cool atmospheres appear much bluer than solar abundance atmospheres at the same effective temperature.

Figure 5 gives a few more examples of the spectra emitted by cool brown dwarf atmospheres. The figure also gives the location of some important filters as well as detection limits for an object at a distance of 50 pc. The spectra correspond to atmospheres with effective temperatures of 2000 K (young brown dwarf), ~1000 K and 500 K (evolved brown dwarf or gas-giant planet). The broad-band absorption features are due to water vapor and, for lower temperatures, bands of methane (CH_4).

Web update

For the first time, an optical coronal line from a star other than the Sun has been detected. The UV-Visual Echelle Spectrograph (UVES) on the VLT 8.2 m KUEYEN telescope at the ESO Paranal Observatory has observed a coronal emission line in nearby variable star CN Leonis from iron ions that have lost 12 electrons (Fe XIII). CN Leonis, a cool star, is located at a distance of 8 light-years.

Stellar Atmospheres: Early Type Stars

The topic 'Stellar atmospheres of early type stars' has two individual ingredients, a (stellar) *atmosphere*, and an *early type star*. We shall specify these two terms in turn.

An *atmosphere* of a star is generally any material connected physically to a star from which the photons escape to the surrounding space. In other words, it is a region where the radiation, observable by a distant observer, originates. Traditionally, the term atmosphere has been understood in a limited sense as a thin layer on the surface of a star. However, the more modern view is that the atmosphere encompasses a region extending far from the star. For instance, the solar corona, which extends even beyond Earth orbit, is understood as a part of the solar atmosphere; from this point of view we all live in a stellar atmosphere.

The term *early type stars* is somewhat loose. Although this class could be meant to comprise all stars that are indeed in the early stages of their evolution, the typical use of this term specifies early type stars as massive hot stars, not necessarily young. Using the common stellar classification, the early type stars typically include stellar classes O, B and early A, but also more evolved stars like luminous blues variables (LBV) and Wolf–Rayet (WR) stars.

The fundamental parameters of a star are mass (M), effective temperature ($T_{\rm eff}$) and total luminosity (L). Effective temperature quantifies the total radiation flux emergent from a surface; precisely, it is the temperature that a black body would have if it was radiating the same total energy flux as the unit area of the actual stellar surface. Typical values of these parameters are $M \approx 8$–100 (or more) times the mass of the Sun ($M_\odot$), $T_{\rm eff} \approx 10\,000$–$50\,000$ K, and $L \approx 10^3$–10^6 times the solar luminosity ($L_\odot$).

One of their most significant properties is a strong outflow of matter from their surfaces, reaching velocities up to several thousand km s^{-1}, i.e. of the order of 1% of the speed of light. This outflow is called stellar wind (see RADIATIVELY DRIVEN STELLAR WINDS FROM HOT STARS). Typical values of the mass loss rate from early type stars are $\dot{M} \approx 10^{-9}$–10^{-5} solar masses per year, although in extreme cases of LBV and WR stars the mass loss rate may reach up to $\dot{M} \approx 10^{-3}\ M_\odot\ {\rm yr}^{-1}$. The wind has a profound significance. First, it significantly changes the path of stellar evolution, because the star may actually lose a large part of its initial mass. Second, the mass loss from young, massive stars significantly enriches the interstellar medium in helium and light metals (the enrichment in heavier elements comes from supernova explosions).

In the global astrophysical context, the early type stars have special significance. They physically influence a large space around them. Most importantly, they produce a large portion of ionizing photons for their host galaxy and surrounding intergalactic space (the only competing objects are quasars, which in some cases may provide the bulk of ionizing radiation). As pointed out above, they enrich the interstellar space in He and light metals because of their wind. From the diagnostic point of view, they also have special significance. They are very bright, and therefore may be studied spectroscopically as individual objects in distant galaxies. Reliable model atmospheres for these stars may therefore yield invaluable independent information about distant galaxies, like chemical composition, and, possibly, reliable distances.

Basic physics of stellar atmospheres

There is a separate article on STELLAR ATMOSPHERES, where this term is explained in substantial detail and generality. Here we present a brief summary of the stellar atmosphere theory to the extent that is relevant to stress particular features of early type atmospheres.

From the physical point of view, a stellar atmosphere is generally a plasma composed of many kinds of particles, namely atoms, ions, free electrons, molecules or even dust grains. In an early type stellar atmosphere, because of the high temperature and strong radiation field, there are typically no molecules or dust grains present, at least in the layers that are traditionally considered as an atmosphere. Nevertheless, molecules and dust may still be present in the very remote parts of an atmosphere.

The total particle density ranges from, say, 10^6 to 10^{16} cm^{-3}. It can be shown that under these densities the elastic collisions between particles are frequent enough to yield very nearly a Maxwellian velocity distribution for all particles; moreover with the same associated kinetic temperature. We refer to it as the *electron temperature*, or simply temperature. It should be stressed that this temperature is shared only by massive particles; massless particles, like photons, do not generally possess an equilibrium distribution and thus a corresponding temperature. This point will be discussed in detail later on.

What makes atmospheres of early type stars so special is the fact that because of the strong and energetic radiation field generated in their interiors, the radiation in their atmospheres is not merely a passive *probe* of the physical state of the atmosphere, but rather an important *energy balance agent*. In other words, radiation in fact determines the structure of the medium, yet the medium is probed only by this radiation. Another important feature is that photons have, under the conditions met in the early type stellar atmospheres, a much larger mean free path than massive particles. This means that radiation is able to transport information to large distances; in other words, radiation *couples* the physical states of rather distant regions of the atmosphere.

The other critical feature that follows from the presence of radiation-induced processes is that the medium is prone to departures from thermodynamic equilibrium. Indeed, the simple fact that we do see a star means that photons must escape from the atmosphere (in fact, this is a very definition of an atmosphere). Hence the photons must be missing from the atmosphere, and thus some elementary atomic transition processes can no longer be balanced, which leads to a non-equilibrium situation.

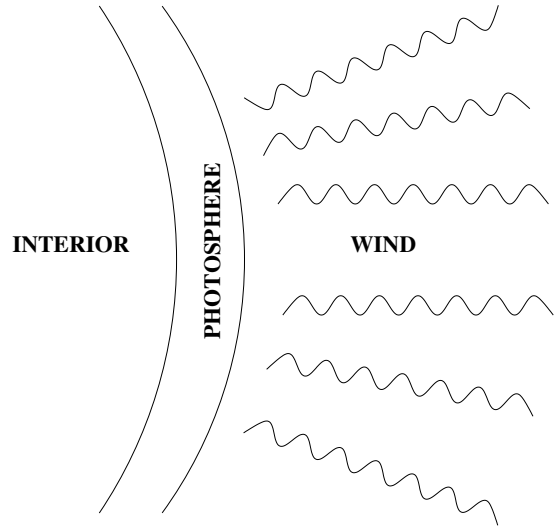

Figure 1. A sketch of basic stellar atmospheric layers. The stellar photosphere is not shown in scale; it would be much thinner.

We shall expand upon this point later. Because of this feature, atmospheres of early type stars have played, and continue to play, an important role not only in the stellar atmosphere theory, but in overall astrophysical radiative transfer theory in general. The whole non-LTE theory (see later) was first developed and tested on early type stellar atmospheres. Consequently, modelling early type stellar atmospheres is a mature field, which may serve as a methodological guide to other astrophysical objects where the radiation also plays an important role, as, for instance, accretion disks in active galactic nuclei (AGN) and in cataclysmic variables (CV), HII regions and others.

Atmospheric layers

Traditionally, an atmosphere of an early type star is divided into two basic regions, schematically displayed in figure 1; the photosphere and the stellar wind.

The photosphere is the innermost part of the atmosphere. The mass outflow velocities are typically very small there, smaller than the local sound speed, so that they can be neglected. The photosphere is thus assumed to be an essentially static region; one of the basic structural equations is thus the hydrostatic equilibrium equation. The radial extent of the photosphere is typically very small compared with the stellar radius, even for hot massive stars.

The stellar photosphere is characterized by the condition of hydrostatic and radiative equilibrium. The hydrostatic equilibrium stipulates that the gradient of the total pressure is balanced by the local gravity acceleration. Because the radial extent of the photosphere is small compared to the stellar radius, the gravity acceleration is essentially constant. The explicit form of this equation is (for a spherically symmetric star)

$$\frac{\mathrm{d}P}{\mathrm{d}R} = -\rho G M_*/R^2 \approx -\rho G M_*/R_*^2 \equiv -\rho g \qquad (1)$$

where P is the total pressure, generally composed of three parts (the gas pressure, P_{gas}, the radiation pressure, P_{rad}, and the turbulent pressure, P_{turb}), R is the radial coordinate, M_* and R_* are the stellar mass and radius respectively, g is the gravity acceleration at the stellar surface and ρ is the mass density.

The radiative equilibrium simply states that the only energy transport mechanism is radiation. In other words, it says that the total radiation energy absorbed in a given elementary volume of material in the photosphere is equal to the total radiation energy emitted in the volume

$$\int_0^\infty (\kappa_\nu J_\nu - \eta_\nu)\,\mathrm{d}\nu = 0 \qquad (2)$$

where κ_ν is the absorption coefficient, η_ν the emission coefficient and J_ν the mean intensity of radiation. (As is customary in astrophysical radiative transfer, a functional dependence on the frequency ν is typographically denoted as a subscript ν standing at the corresponding quantity.) Equation (2) also states that the energy is only *transported* in the photosphere; there is no energy *generated* there. This makes a sharp distinction from the stellar interior (where the energy is generated by nuclear reactions), and from the other atmospheric layers (e.g. stellar chromospheres, coronas or winds), where the energy is generated by dissipation of various wave motions.

It can be easily shown that the atmospheres of early type stars are convectively stable; this feature marks a significant difference from the atmospheres of cooler stars (type late A and later), where convection is another significant mechanism of energy transfer. Roughly speaking, the convection is a transport of energy by rising and falling bubbles of material with properties (e.g. temperature) different from the ambient medium.

The stellar wind is the region where the outflow velocities are comparable to or larger than the local sound speed. The radial extent of this region may be comparable to or, in some cases, significantly larger than, the radius of the stellar photosphere. This region is comprehensively reviewed in a separate article.

In some cases there may be a third, more remote, layer which may contain molecules and dust. For instance, very young stars may still be enveloped by their placental matter. These regions are probed by the infrared and radio radiation (see also STAR FORMATION, INTERSTELLAR MOLECULAR CLOUDS, etc).

Microscopic processes

From the very nature of stellar atmospheres it is clear that the detailed description of the processes of interaction between radiation and matter is a crucial ingredient of the stellar atmospheres theory. These processes determine (a) how the radiation is transported in the atmosphere, and (b) what is the distribution of the microscopic degrees of freedom of the massive particles (e.g. the excitation and ionization state of the individual atomic species, etc).

The interaction between radiation and matter is described phenomenologically through the radiative transfer equation

$$\left(\frac{1}{c}\frac{\partial}{\partial t} + \boldsymbol{n}\cdot\nabla\right) I(\nu, \boldsymbol{r}, \boldsymbol{n}, t) = \eta(\nu, \boldsymbol{r}, \boldsymbol{n}, t) - \chi(\nu, \boldsymbol{r}, \boldsymbol{n}, t) I(\nu, \boldsymbol{r}, \boldsymbol{n}, t). \quad (3)$$

Here, I is the specific intensity of radiation, defined such that it is the energy transported by radiation in a unit frequency range at the frequency ν, across a unit area perpendicular to the direction of propagation, $\boldsymbol{n}$, into a unit solid angle, and in a unit time interval. The specific intensity provides a complete description of the unpolarized radiation field from the macroscopic point of view. (This description can be generalized to an arbitrarily polarized light by introducing the Stokes vector instead of the scalar intensity, but we will not consider this concept in this article, and assume an unpolarized radiation, which is quite appropriate in the context of early type stars.)

Quantities χ and η are phenomenologically defined as absorption and emission coefficients, respectively. They are defined analogously to the specific intensity, namely as the energy removed or added to a beam of radiation at unit frequency range, solid angle, area and time.

It is known from the quantum theory of radiation that there are three types of elementary processes that give rise to an absorption or emission of a photon: (a) induced absorption—an absorption of a photon accompanied by a transition of an atom/ion to a higher energy state; (b) spontaneous emission—an emission of a photon accompanied by a spontaneous transition of an atom/ion to a lower energy state; and (c) stimulated emission—an interaction of an atom/ion with a photon accompanied by an emission of another photon with identical properties. In the astrophysical formalism, the stimulated emission is usually treated as negative absorption.

In thermodynamic equilibrium, the microscopic detailed balance holds, and therefore the radiation energy absorbed in an elementary volume in an elementary frequency interval is exactly balanced by the energy emitted in the same volume and in the same frequency range, i.e. $\chi I = \eta$. Moreover, in thermodynamic equilibrium, the radiation intensity is equal to the Planck function, $I = \mathrm{B}$, where

$$B(\nu, T) = \frac{2h\nu^3}{c^2}\frac{1}{\exp(h\nu/KT) - 1}. \quad (4)$$

We are then left with an interesting relation that in thermodynamic equilibrium $\eta/\chi = \mathrm{B}$, which is called *Kirchhoff's law*.

The absorption and emission coefficients are written explicitly as

$$\chi_\nu = \sum_i \sum_{j>i} [n_i - (g_i/g_j) n_j]\sigma_{ij}(\nu) + \sum_i (n_i - n_i^* \mathrm{e}^{-h\nu/kT})\sigma_{i\kappa}(\nu) + \sum_\kappa n_\mathrm{e} n_\kappa \sigma_{\kappa\kappa}(\nu, T)(1 - \mathrm{e}^{-h\nu/kT}) + n_\mathrm{e}\sigma_\mathrm{e} \quad (5)$$

where the four terms represent, respectively, the contributions of bound–bound transitions (i.e. spectral lines), bound–free transitions (continua), free–free absorption (also called bremsstrahlung), and of electron scattering. In the stellar atmospheric conditions the electron scattering is to a good approximation coherent (i.e. without a change of photon frequency—Thomson scattering). A more general case, with a decrease or increase of the photon energy (frequency), is called Compton or inverse Compton scattering respectively. Typically, the effects of Compton scattering are negligible in the atmospheres of early type stars (they may be important in the atmospheres of very hot subdwarfs, white dwarfs and pre-white dwarfs). In principle, other scattering terms, like for instance Rayleigh scattering, may also be added if needed.

In equation (5) n_i is the occupation number (population) of an atom in the energy level labelled i, g_i the corresponding statistical weight and n_i^* denotes an equilibrium population of level i corresponding to temperature T and electron density n_e. $\sigma(\nu)$ are the corresponding cross sections; subscript κ denotes the 'continuum', and n_κ the ion number density. The negative contributions in the first three terms represent the stimulated emission. There is no stimulated emission correction for the scattering term, because this contribution exactly cancels with ordinary absorption. The relation between the bound–bound cross section $\sigma_{ij}(\nu)$ and the well-known Einstein coefficients for the photoexcitation is $\sigma_{ij}(\nu) = (h\nu_0/4\pi)B_{ij}\phi(\nu)$; $\phi(\nu)$ is the so-called *absorption profile coefficient*, normalized to unity, $\int \phi(\nu)\,\mathrm{d}\nu = 1$. It represents the conditional probability density that if a photon is absorbed in the transition $i \to j$, it is absorbed in the frequency range $(\nu, \nu + \mathrm{d}\nu)$.

Analogously, the thermal emission coefficient is given by

$$\eta_\nu = \frac{2h\nu^3}{c^2}\left(\sum_i \sum_{j>i} n_j (g_i/g_j)\sigma_{ij}(\nu) + \sum_i n_i^* \sigma_{i\kappa}(\nu)\,\mathrm{e}^{-h\nu/kT} + \sum_\kappa n_\mathrm{e} n_\kappa \sigma_{\kappa\kappa}(\nu, T)\,\mathrm{e}^{-h\nu/kT}\right). \quad (6)$$

The three terms again describe the bound–bound, bound–free and free–free emission processes respectively.

The absorption and emission coefficients are thus described through the corresponding cross sections—given by the atomic physics, the local thermodynamic parameters, T and n_e, and the atomic level populations for all the levels involved in the microscopic processes that give rise to an absorption and emission at frequency ν; such a number may be enormous. The chief difficulty of the stellar atmospheres theory is that the level populations generally depend on other state parameters and the radiation field.

LTE versus non-LTE

It is well known from statistical physics that a description of material properties is greatly simplified if the thermodynamic equilibrium (TE) holds. In this state, the particle velocity distributions as well as the distributions of atoms over excitation and ionization states are specified uniquely by two thermodynamic variables. In the stellar atmospheres context, these variables are usually chosen to be the (kinetic) temperature (T), and the total particle number density (N), or the electron number density (n_e). From the very nature of a stellar atmosphere it is clear that it cannot be in thermodynamic equilibrium—we *see* a star, therefore we know that photons must be escaping. Because photons carry significant momentum and energy, the elementary fact of photon escape has to give rise to significant gradients of the state parameters in the stellar outer layers.

However, even if the assumption of TE cannot be applied to a stellar atmosphere, we may still use the concept of local thermodynamic equilibrium (LTE). This assumption asserts that we may employ the standard thermodynamic relations not globally for the whole atmosphere, but *locally*, for local values of $T(\boldsymbol{r})$ and $N(\boldsymbol{r})$ or $n_e(\boldsymbol{r})$, despite the gradients that exist in the atmosphere. This assumption simplifies the problem enormously, for it implies that all the particle distribution functions may be evaluated locally, without reference to the physical ensemble in which the given material is found. Notice that the equilibrium values of distribution functions are assigned to *massive particles*; the radiation field is allowed to depart from its equilibrium, Planckian, distribution function (i.e. $I = \mathrm{B}$ is valid only in strict TE).

Specifically, LTE is characterized by the following three distributions:

- Maxwellian velocity distribution of particles;
- Boltzmann excitation equation;
- Saha ionization equation.

Microscopically, LTE holds if all atomic processes are in *detailed balance*, i.e. if the number of processes $\mathrm{A} \rightarrow \mathrm{B}$ is exactly balanced by the number of inverse processes $\mathrm{B} \rightarrow \mathrm{A}$. By A and B we mean any particle states between which there exists a physically reasonable transition. For instance, A is an atom in an excited state and B the same atom in another state (either of the same ion, in which case the process is an excitation/de-excitation; or of the higher or lower ion, in which case the term is an ionization/recombination).

In contrast, by the term non-LTE (or NLTE) we mean any state that departs from LTE. In practice, one usually means that populations of some selected energy levels of some selected atoms/ions are allowed to depart from their LTE value, while the velocity distributions of all particles are assumed to be Maxwellian, all at the same local kinetic temperature, T.

One of the big issues of modern stellar atmosphere theory is whether, and if so to what extent, departures from LTE should be included in numerical modelling. Generally, to understand why and where we may expect departures from LTE, let us turn to the microscopic definition of LTE. It is clear that LTE breaks down if the detailed balance in at least one transition $\mathrm{A} \rightarrow \mathrm{B}$ breaks down. We distinguish the *collisional transitions* (arising due to interactions between two or more massive particles) and *radiative transitions* (interactions involving particles and photons). Under stellar atmospheric conditions, collisions between massive particles tend to maintain the local equilibrium (because velocities are Maxwellian). Therefore, the validity of LTE hinges on whether the radiative transitions are in detailed balance or not.

Again, the fact that the radiation escapes from a star implies that LTE should eventually break down at a certain point in the atmosphere. Essentially, this is because detailed balance in radiative transitions generally breaks down at a certain point near the surface. Because photons escape (and more so from the uppermost layers), there must be a lack of them there. Consequently, the number of photoexcitations (or any atomic transition induced by absorbing a photon) is less than the number of inverse processes, spontaneous de-excitations (we neglect here, for simplicity, stimulated emission).

These considerations explain that we may expect departures from LTE if the following two conditions are met: (a) radiative rates in some important atomic transition dominate over the collisional rates; and (b) radiation is not in equilibrium, i.e. the intensity does not have a Planckian distribution. Because the collisional rates are proportional to the particle density, the departures from LTE tend to be small for high densities. Likewise, deep in the atmosphere, photons do not escape, and so the intensity is close to the equilibrium value. Departures from LTE are therefore small, even if the radiative rates dominate over the collisional rates. On the other hand, departures from LTE are important for low-density media immersed in a strong radiation field, which are precisely the conditions met in the atmospheres of early type stars.

Model atmospheres

By the term model stellar atmosphere we mean a specification of all the atmospheric state parameters as functions of position. These parameters are obtained by solving appropriate structural equations, which, in the case of stellar photospheric models, are the equations of hydrostatic equilibrium, radiative equilibrium, radiative transfer equation, and the set of statistical equations (rate equations) for the atomic level populations. In the case of LTE models, the rate equations are not needed because the level populations are given by the Saha–Boltzmann distribution. Because the problem is very complex, it is impossible to find analytical solutions. Therefore, we have to resort to numerical simulations. In order to make the overall problem tractable, one has to make a number of simplifications by invoking various approximations. The quality of an appropriate model, and consequently its applicability to the individual stellar

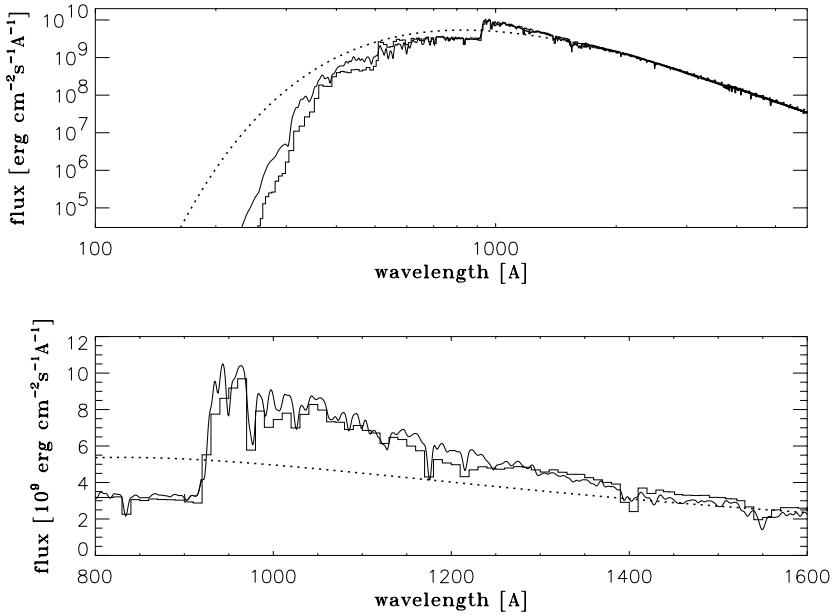

Figure 2. A comparison of the predicted flux from the fully blanketed NLTE model atmosphere with $T_{\rm eff} = 35\,000$ K, $\log g = 4$ (heavy curve); the Kurucz LTE line-blanketed model for the same parameters (thin histogram); and a black-body flux for $T = T_{\rm eff} = 35\,000$ K (dotted curve). The upper panel dispays the flux in a wide range of wavelengths (notice the logarithmic ordinate), while the lower panel shows the flux (in the linear scale) in the vicinity of the Lyman limit. The flux was convolved with Gaussian broadening with FWHM = 5 Å.

types, is closely related to the degree of approximation used in the construction of the model. Needless to say, the degree of approximation critically influences the amount of computational effort to compute it. It is fair to say that the very art of computing model stellar atmospheres is to find such physical approximations that allow the model to be computed with a reasonable amount of numerical work, yet the model is sufficiently realistic to allow its use in reliable interpretation of observed stellar data. The adopted approximations are therefore critical. There are several types of approximations that are typically made during model construction; we shall describe the most important types in turn.

Approximations of the geometry

By geometrical simplification we mean that either some prescribed geometrical configuration is assumed, or some special kind of overall symmetry is invoked. The goal of those simplifications is to reduce the dimensionality of the problem from a spatially three-dimensional problem to a 1- or 2D problem. The most popular approximations are (from simplest to more complex):

(a) Plane parallel geometry, with an assumption of horizontally homogeneous layers. This decreases the number of dimensions to one: the depth in the atmosphere. This approximation is typically quite reasonable for stellar photospheres, which indeed are thinner by several orders of magnitude than the stellar radius, so the curvature effects are negligible. The assumption of horizontal homogeneity is made for the sake of simplicity—there is no plausible verification of this approximation, and, moreover, observational evidence mostly shows that stellar surfaces are far from being homogeneous (a notorious example being detailed pictures of the solar surface). Nevertheless, even in the presence of inhomogeneities, 1D models still have their value since in many cases one may construct different 1D models for the individual 'patches' on the surface.

(b) Spherical symmetry. Again, the problem is one-dimensional. The approach is used for extended atmospheres, for which the atmospheric thickness in no longer negligible with respect to the stellar radius. Typically, we have to consider such models for early type giants and supergiants, as well as for earliest types of main-sequence O stars.

(c) Multidimensional geometry. This field is in its infancy. A numerical solution is extremely demanding on computer time and memory, and only very recently has computer power reached a stage that calculating such models is becoming feasible. Some detailed model atmospheres including 2D and 3D geometry have been constructed for a solar atmosphere, and some 2D simulations of early type stellar winds have been performed.

Approximations of the dynamical state of the atmosphere

This is basically a specification of the realism of the treatment of the macroscopic velocity fields. From the

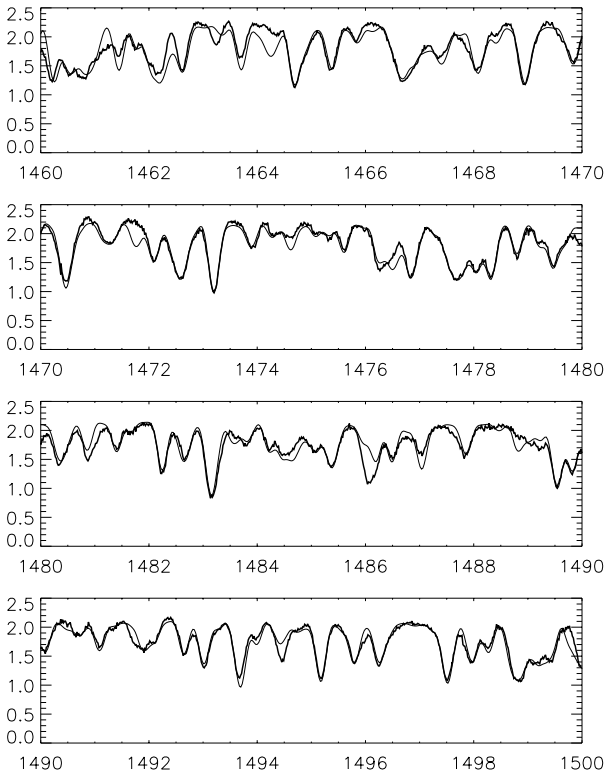

Figure 3. A comparison of the observed HST/GHRS flux for 10 Lac (heavy curve) and the predicted flux from the fully blanketed NLTE model atmosphere with $T_{\rm eff} = 35\,000$ K, $\log g = 4$ and $v \sin i = 25$ km s^{-1}, and for the solar abundances of all species. The predicted flux is convolved with instrumental broadening with FWHM = 0.06 Å. The abscissa is the wavelength in Å, and the ordinate is the flux in 10^{-9} erg cm^{-2} s^{-1} Å^{-1}. Most spectral features are lines of Fe IV, Fe V, Ni IV and Ni V.

simplest to the most complex the approaches are the following:

(a) Static models, in which the macroscopic velocity field is set to zero. As discussed above, these models describe a *stellar photosphere*.
(b) Models with an *a priori* given velocity field. In these models the velocities are taken into account explicitly, and their influence upon other state parameters, in particular the emergent radiation, is studied in detail. In these models, one can either consider only a dynamical region (i.e. the wind) and take the incoming radiation from the photosphere as given *a priori*—the so-called core-halo model—or a model which treats the photosphere and the wind on the same footing. Such models are called *unified models*.
(c) Models where the velocity field is determined self-consistently by solving the appropriate hydrodynamical equations. This problem is very complicated because the wind driving force is given by the absorption of photons in thousands to millions of metal lines (the so-called line-driven wind, so the hydrodynamical equations should be solved together with at least an approximate treatment of radiative transfer in spectral lines.

Approximations of the opacity sources

In real stellar atmospheres, there are an enormous number of possible opacity sources. It is impractical to take all of them into account in full detail. The light elements (H, He, C, N, O) have a comparatively small number of lines per ion (say 10^2 to 10^4) because of a relatively simple atomic level structure. The number of lines generally increases with increasing atomic number, and for the iron-peak elements (Fe and Ni being the most important ones), we have of the order of 10^6 to 10^7 spectral lines per ion! Therefore, the opacity (and emissivity) may be an enormously complicated function of frequency.

There are several approximations that are to meant to reduce this complexity considerably:

(a) Models constructed using certain frequency-averaged opacities; these models are called *grey* models. The approach is based on the implicit assumption that the behaviour of the frequency-averaged intensity of radiation is well described by means of some frequency-averaged opacities. There are several possible mean opacities, depending on exactly how the averaging is done. The most used averaged opacity is the *Rosseland mean* opacity, defined by

$$\frac{1}{\chi_{\rm R}} \equiv \frac{\int_0^\infty (1/\chi_\nu)(\mathrm{d}B_\nu/\mathrm{d}T)\mathrm{d}\nu}{\int_0^\infty (\mathrm{d}B_\nu/\mathrm{d}T)\,\mathrm{d}\nu} \qquad (7)$$

where χ_ν is the opacity (per gram of stellar material). Because averaging is done for $1/\chi$, the largest weight is given to regions of lowest opacity, which are the most efficient regions for the energy flux transport. This explains why the Rosseland mean opacity is well suited for describing the total radiation flux. The grey model atmospheres are no longer used for spectroscopic analysis, but they are useful for providing an initial estimate in any iterative method for constructing more realistic model atmospheres, and they are very useful for pedagogical purposes because they allow one to understand a rough behaviour of temperature and radiation field as a function of depth in the atmosphere.
(b) A possibility is to use stepwise frequency averages for a number of subintervals (frequency bins), sometimes called the multifrequency/multi-grey method. This approach is used in constructing model stellar atmospheres only rarely, but is used in other branches of astrophysical and laboratory radiative transfer.
(c) A completely different approach is to construct a model atmosphere neglecting the line opacity completely. Although this may seem very crude, such models may actually provide reasonable results for very metal-poor stars because, as was pointed

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

put above, H and He posses only a small number of lines, which occupy only a very small frequency range and therefore have a small influence on the model structure. (Strictly speaking, this is not completely true, because just three of the most important hydrogen lines, Lα, Lβ and Hα, may already have an important indirect effect upon the temperature structure in the outer layers of early type photospheres.) In any event, this approximation was introduced at the early stages of development of the non-LTE model atmospheres, and was motivated by limitations of the then available computers and numerical techniques.

(d) The obvious next level of approximation is to consider a small number of lines (typically tens to hundreds) explicitly, while neglecting the bulk of metal lines; the selected lines are those which presumably have the largest effect upon the atmospheric structure.

(e) Finally, one can take into account, one way or another, 'all' metal lines. Such models are traditionally called *metal line-blanketed model atmospheres*. The problem of constructing such models is computationally very demanding. Under the assumption of LTE it is, however, considerably simplified because the opacity and emissivity is a function of only local temperature and electron density; the only problem is the complicated frequency dependence of the opacity. Without the approximation of LTE the problem is significantly more difficult because one has to determine all the atomic level populations and temperature self-consistently with the radiation field.

Approximations concerning the thermodynamic equilibria

Here, as we discussed above, the issue is whether the approximation of LTE is adopted or not. If we assume LTE, the resulting model atmospheres are called LTE models. Two state parameters, the temperature, T, and density, ρ (or electron density, n_e), suffice to describe the physical state of the atmosphere at any given position. In practice, LTE models may be useful only for stellar photospheres, because for extended atmospheres and/or stellar winds this approximation breaks down completely and its application would yield erroneous and misleading results.

The models that take some kind of departure from LTE into account are called non-LTE (or NLTE) models. This term is rather ambiguous because it is not *a priori* clear what is actually allowed to depart from LTE in a given model. In early models, the populations of only a few low-lying energy levels of the most abundant species, like H and He, were allowed to depart from LTE; the rest were treated in LTE. During the development of the field, progressively more and more levels were allowed to depart from LTE. The situation is similar for stellar photospheres (static models), as well as for stellar winds and for unified models.

Existing model atmospheres

Because stellar winds are covered in a separate article, we concentrate here on static models, i.e. models of early type stellar photospheres.

The most extensive grid of LTE line-blanketed models is that of Kurucz; the grid covers effective temperatures between 3500 K and 50 000 K, so that it includes stars much cooler than early type stars.

During the last three decades, it has been amply demonstrated that departures from LTE are crucial for spectroscopic studies of early-type stars, even the photospheric layers. Early non-LTE models were constructed as early as the late 1960s and in the first half of the 1970s by Mihalas and co-workers. Nevertheless, the numerical problems and the sheer amount of computer time and memory needed for computing non-LTE metal line-blanketed model atmospheres precluded computing such models until the late 1980s. Thanks to the development of a very efficient numerical method for solving the radiative transfer equation simultaneously with other state equations, called the accelerated lambda iteration (ALI) method (see RADIATIVE TRANSFER), this last barrier to tackling the classical stellar atmosphere problem was broken, and non-LTE metal line-blanketed models including literally millions of spectral lines in non-LTE are now being constructed. Because sufficiently efficient computer codes for mass production of non-LTE line-blanketed models were being developed only during the mid 1990s, there is no comprehensive grid of non-LTE line-blanketed models which would cover the same range of parameters as the Kurucz grid, currently available, but they will very likely be built in the coming years.

From the practical point of view, the most important result of model atmospheres is the prediction of emergent radiation, which is then compared with the observed spectrum in order to deduce basic stellar parameters. Also, theoretical predictions are indispensable for estimating the radiation in unobservable spectrum regions, in particular in the hydrogen Lyman continuum (wavelength less than 912 Å), which produces ionizing photons but which cannot be directly detected for early type stars because of the absorption by interstellar hydrogen. (Only two early type stars, ϵ and β CMa, which are relatively close, and which lie in the direction of a 'tunnel' of low density in the local interstellar medium, have detectable Lyman continuum flux as observed by the EUVE satellite.)

Figure 2 presents a comparison of predicted flux for a star with $T_{\rm eff} = 35\,000$ K, $\log g = 4$, which corresponds to a main-sequence late O type star. The difference between the LTE and non-LTE predictions is important, particularly in the extreme UV region. For completeness, a black-body flux for $T = T_{\rm eff}$ is also displayed. The black-body flux is obviously no longer used for any analysis of spectra of early type stars, but is still sometimes being used in other branches of astrophysics, like cosmology, for estimating the total number of ionizing photons produced by young, massive stars. As this figure shows, such estimates may be wrong by several orders of magnitude.

As an example of a detailed predicted spectrum from a modern, non-LTE metal line-blanketed model atmosphere, we present in figure 3 a sample of the predicted flux for a non-LTE model for $T_{\rm eff} = 35\,000$ K, $\log g = 4$, and a high-resolution, high signal-to-noise observation of a late O main-sequence star 10 Lac secured by the Goddard High Resolution Spectrograph (GHRS) aboard the Hubble Space Telescope (HST). The agreement between observations and predictions is excellent, and demonstrates the power of the present-day model atmospheres of early type stars.

Model stellar atmospheres are basic tools for analysing observed stellar spectra. By fitting the observed spectrum with a grid of theoretically predicted spectra one can derive the basic parameters used for constructing the models, i.e. the effective temperature, surface gravity, chemical composition, and, in the general case, the mass loss rate. From those parameters, one can derive the fundamental stellar parameters, like the mass, radius and luminosity. Besides these, there are a number of secondary parameters, such as the rotational velocity, or auxiliary parameters describing the nature of atmospheric velocity fields, etc. Detailed techniques for determining those parameters are described in separate articles (CHEMICAL COMPOSITIONS OF STARS, STELLAR DISTRIBUTIONS, LUMINOUS BLUE VARIABLES, STELLAR MASSES, CLASSIFICATION OF STELLAR SPECTRA). Here we just mention that thanks to modern, sophisticated model atmospheres, the typical accuracy of determining the effective temperature of early type stars is about 5%, the accuracy in $\log g$ about 0.1–0.2 dex, and the accuracy of chemical abundances about 0.2–0.3 dex.

Bibliography

The fundamental textbook of the field is

Mihalas D 1978 *Stellar Atmospheres* 2nd edn (San Francisco: Freeman)

A good textbook that covers both the theoretical and observational aspects of the stellar atmospheres is

Gray D F 1992 *Observations and Analysis of Stellar Photospheres* 2nd edn (Cambridge: Cambridge University Press)

Other related textbooks on physical aspects of radiative transfer include

Stellar Diameters

The radius of a star is one of several fundamental stellar parameters, including its mass and the luminosity, that characterize the physical and the evolutionary state of a star. A combination of parameters such as mass, luminosity, effective temperature and radius determines the location of a star in the H–R diagram.

Over the past century a number of direct and indirect methods of measuring stellar radii have been developed. The most straightforward method is by measuring the angular diameter ϕ and combining it with the known distance to the star:

$$R = \text{distance} \times \phi.$$

However, because of the very large distances of stars, and in spite of their large size (ranging from $0.01 R_\odot$ to over $1000 R_\odot$), their angular diameters are very small and difficult to measure directly. For example Proxima Centauri, the closest star to the Sun, has an angular diameter of only 0.006 arcsec. Even the largest stellar angular diameters are only a few hundredths of an arcsecond.

Furthermore, it is not easy to define a radius of a star even assuming that the stellar surface can be approximated with a sphere. If the stellar surface was uniformly bright and there was a sharp limb at a distance R from the center of the stellar disk where the intensity drops to 0, then we could say that R corresponds to the radius of the star. However, since stars are gaseous objects their continuum intensity, $I_\lambda(\theta)$, varies from the center ($\theta = 0$) toward the limb ($\theta > 0$), where θ is the angle between the line of sight and the radial vector. Even for relatively compact stars such as our Sun the brightness of the photosphere varies from the center toward the limb. The center-to-limb intensity variation of a solar-type star can be described by the following relation:

$$I_\lambda(\theta)/I_\lambda(0) = 1 - u_2 - v_2 + u_2 \cos\theta + v_2 \cos^2\theta$$

where the average values for the Sun are $u_2 = +0.84$, $v_2 = -0.20$; the dependence on wavelength for $0.20\ \mu\text{m} < \lambda < 10\ \mu\text{m}$ is given in Cox (2000).

In the following we describe several direct and indirect diameter measurement techniques and highlight results obtained from ground- and space-based observations.

Angular diameters

Measurement techniques

Direct measurements of stellar angular diameters can be obtained using several high-angular-resolution techniques including imaging with large-aperture telescopes, lunar occultation and interferometry.

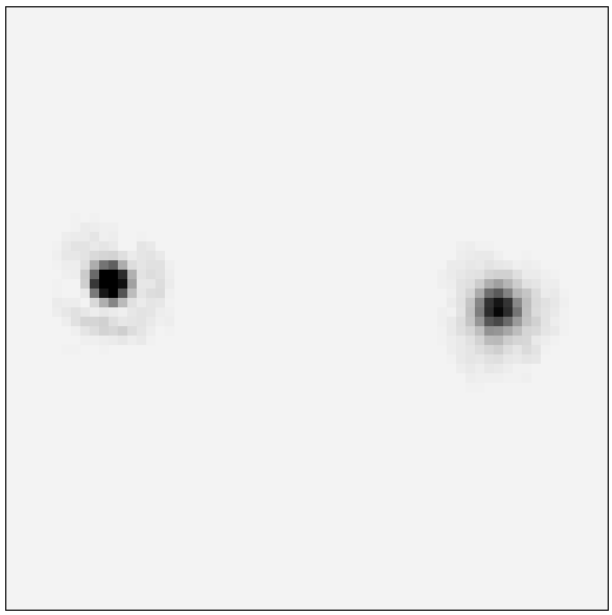

Figure 1. Diffraction-limited HST images of Mira (right) and its companion (left) at 5010 Å.

Large-aperture telescopes. Large-aperture telescopes are necessary to measure stellar angular diameters because the larger the APERTURE, the smaller is the angle on the sky that can be resolved. The size of the aperture of a telescope determines its theoretical diffraction-limited angular resolution at a given wavelength. The resolving power of a telescope increases as the wavelength of observation decreases. For example, to resolve Proxima Centauri at optical wavelengths one needs a telescope with an aperture of about 25 m.

A telescope image of an astronomical source obtained in the absence of atmospheric turbulence (e.g. from space) can be mathematically described as the convolution of the brightness distribution of the source with a blurring function introduced by the limited aperture of the telescope and the finite size of detector pixels. According to the Nyquist criterion, detector pixel size must be less then 1/2 the diffraction limit of the telescope in order to obtain diffraction-limited observations.

As an example of diffraction-limited observations from space, figure 1 shows an image of the Mira AB system obtained using the 2.5 m aperture Hubble Space Telescope (HST) and the Faint Object Camera at 5010 Å (Karovska *et al* 1997). The primary o Ceti (Mira), the prototype of Mira-type variables, is an evolved giant, and the secondary VZ Ceti is a white dwarf. The separation between the components is only 0.6 arcsec (or about 60 AU using a distance to Mira of 100 pc).

The diffraction-limited image of Mira appears substantially larger than the image of the companion and is clearly resolved by the 2.5 m telescope. The companion is unresolved by the telescope and one can discern the

Dirac House, Temple Back, Bristol, BS1 6BE, UK

diffraction ring in its image. The diffraction limit of the HST in the optical is about 50 marcsec (mas). The size of the detector's pixels is approximately three times smaller, 14 mas. The measured size of Mira's atmosphere at this wavelength is 60 mas, which corresponds to approximately 6 AU.

If similar observations of this system were carried out using a 2.5 m ground-based telescope, the binary would have been barely resolved because the images would have been blurred by the atmospheric SEEING. The seeing-limited size of each individual image would have been comparable with the size of the binary separation in the system.

Modern adaptive and/or active optics techniques are used to correct and compensate for the seeing effects which degrade the resolution of the ground-based observations. These techniques allow reaching the full diffraction-limited resolution of large-aperture ground-based telescopes (see INSTRUMENTATION: ADAPTIVE OPTICS).

Lunar OCCULTATION is another way to measure angular diameters in the presence of Earth's atmosphere. The lunar occultation technique uses the diffraction phenomenon occurring as the Moon's sharp limb occults the stellar disk. The resolution in this case is not limited by the diffraction limit of the single-aperture telescope. Several hundred angular diameter measurements have been made so far (Richichi *et al* 1996). This method is limited only to a set of stars that can be occulted by the Moon.

Interferometric techniques using two or more apertures provide another means of improving the resolution in the ground-based observation, and of measuring angular diameters. These techniques are also very promising for future high-angular-resolution observations from space.

Interferometry. In 1920 Michelson and Pease found a way to enhance the resolution of the ground-based observations degraded by the atmospheric seeing effects by using a technique based on the interference of the light from two mirrors in an INTERFEROMETER. The baseline (the separation between the interferometer mirrors) defines the resolution power of an interferometer; at a given wavelength, the resolution power increases as the baseline increases.

At Mt Wilson Michelson and Pease constructed two interferometers (with approximately 7 m and 17 m baselines). They used these interferometers to make the first direct measurements of the angular sizes of stars other then our Sun. For example, they measured diameters of two variable stars, the red supergiants α Ori and α Sco over a period of 17 yr. Assuming uniform brightness distribution on the stellar disk, they obtained diameter measurements of α Ori ranging from 34 mas to 54 mas. For α Sco, the measured diameters range from 28 mas to 40 mas. Other interferometric measurements followed, including diameter measurements of early-type stars using the Narrabri Stellar Intensity Interferometer (Hanbury Brown *et al* 1974).

In 1975, Labeyrie applied a novel approach to eliminate the degrading effects of the atmosphere on the ground-based images. Using a technique called speckle interferometry, which is based on light interference in a single-aperture telescope, he resolved the components of the binary system Capella (separated at only 50 mas) using the Mt Palomar 5 m aperture telescope. The separation between the components of this system is 10–20 times smaller than the size of the direct image of the system degraded by the atmospheric seeing (see also SPECKLE IMAGING OF BINARY STARS).

Labeyrie and his group measured the diameters of several VARIABLE STARS using the speckle interferometric technique, including evolved giants such as Mira and R Leo. The measurements were made assuming a uniform brightness distribution on the stellar disk (Labeyrie *et al* 1977). The results showed that within the same pulsation phase there is a significant variation in the diameter measurements obtained using filters centered in different spectral regions. These variations are explained as due to stratification of the extended atmosphere of these evolved stars.

Today there are more then a dozen ground-based interferometers around the world operating at wavelengths ranging from optical to IR, and at radio wavelengths. Their baselines range from a few meters to several hundred meters (see INTERFEROMETRY: GROUND). Other groups are successfully applying single-aperture interferometric techniques, such as speckle interferometry and non-redundant aperture masking, for high-angular-resolution observations of stars.

Several feasibility studies are at present being carried out for interferometers in space. The beginning of the 21st century may see the first prototype interferometers in space (e.g. SIM; DARWIN), which will open new frontiers in stellar astrophysics.

Examples of angular diameter measurements

A plethora of multiwavelength measurements of the angular size of many stars have been obtained using various high-angular-resolution techniques at wavelengths ranging from UV to radio spectral domain. Recently, diameter measurements have also been made from space using direct imaging with the HST and interferometry with the HST Fine Guidance Sensors (see ASTROMETRY WITH HUBBLE SPACE TELESCOPE). In the following we highlight some of these results.

Giants and supergiants

High-angular-resolution observations of evolved giants and supergiants can provide important information on the structure of their extended atmospheres and circumstellar environments. For example, accurate determination of their photospheric angular diameters is crucial for establishing the effective temperature scale (Ridgway and Joyce 1980). The effective temperature can be determined from the relation

$$T_{\rm eff} = (4F/\sigma\phi^2)^{1/4}$$

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

where F is the apparent bolometric flux received on the Earth, ϕ is the photospheric angular diameter and σ the Stefan–Boltzmann constant.

For pulsating stars such as MIRA VARIABLES, an accurately measured photospheric angular diameter when combined with the measured distance to the star yields its linear diameter which can then be used to determine the mode of pulsation (Ostlie and Cox 1986). At present, it is uncertain whether the oscillation mode of Mira-type variables is a fundamental or a first overtone. Once the pulsation mode is determined, it will be possible to better define the evolutionary place of Mira variables and their relation to other types of long-period variables (LPVs) (Willson 1982; van Belle *et al* 1996).

Angular diameter measurements of numerous giants and supergiants have been carried out at wavelengths ranging from the optical to the radio spectral domains. Diameters as small as few milliarcseconds have been measured using interferometric and lunar occultation techniques in optical and infrared. These include for example the high-precision diameter measurements of cool giants at optical wavelengths obtained using the Mk III stellar interferometer (Quirrenbach *et al* 1993) and in the near-infrared using IOTA (van Belle *et al* 1996).

High-angular-resolution observations of evolved giants and supergiants have been carried out in the optical using large single-aperture telescopes (using non-redundant aperture masking technique and speckle interferometry) and lunar occultation techniques (e.g. White 1980; Bonneau *et al* 1982; Haniff *et al* 1995).

Recent observations made using ISI have measured for the first time the diameters of several late-type evolved stars in the mid-infrared spectral domain, at 11 μm wavelength range. They detected dust shells around most of the stars on their list. The measured inner radius of these dust shells ranges from about 2 to several dozen stellar radii. The results of this survey are described in Danchi *et al* (1994).

The sizes of the radio photospheres of several LPVs (Miras and semiregular variables) have been measured using the VLA at the centimeter wavelength range (Reid and Menten 1997). Their observations suggest that these stars have a radio photosphere near 2 stellar radii, where the stellar radius is defined by line-free regions of the optical spectrum.

The multiwavelength diameter measurements were made using models ranging from uniform disk and Gaussian distribution to brightness distributions calculated from various model atmospheres, to estimate the affects of brightness non-uniformity (e.g. Haniff *et al* 1995; van Belle *et al* 1996). The current models often produce a very simplified and usually incomplete description of the physical characteristics of the extended atmosphere because they do not simultaneously incorporate crucial elements such as pulsation, opacities and dust. Stellar size measurements based on inadequate models produce a large scatter in the estimated diameters (e.g. van Belle *et al* 1996) which can bias the calculated effective temperature scale and will affect the accuracy of the derived mode of pulsation.

In addition, current models assume that the atmosphere is spherically symmetric, despite the fact that currently there is substantial evidence that the late-type evolved stars are not symmetric. Recent imaging of several giants and supergiants carried out using ground-based telescopes and the HST detected substantial asymmetries in the extended atmosphere of these stars (Karovska *et al* 1991; Haniff *et al* 1992; Wilson *et al* 1992; Tuthill *et al* 1994; Karovska *et al* 1997). The cause(s) of the observed asymmetries are being explored. The asymmetries could be due to unresolved bright spots on the surface of the star or in the extended atmosphere. They could be related to the pulsation process; plausible mechanisms include instabilities in the pulsating atmospheres and non-radial pulsation.

It is clear that detailed modeling of the extended atmospheric structure is necessary for an accurate determination of the photospheric diameter. Key input parameters that must be measured with high accuracy include diameters in selected spectral regions and the brightness distribution across the stellar disk as a function of wavelength and pulsation phase.

Further progress in understanding the structure of the atmosphere of evolved giants and supergiants depends not only on the results of the multiwavelength interferometric observations but also on the further development of more realistic models incorporating asymmetries, proper abundance information and physical processes such as propagation of shock waves and dust formation. These models should produce phase-dependent brightness distributions in selected spectral regions important for atmospheric structure diagnostics such as different molecular bands, the continuum (UV, optical and especially in the near-IR) and emission lines carrying shock signatures (see also STELLAR ATMOSPHERES).

Cepheids. Among the pulsating stars, Cepheids are most notable because of their importance for establishing the primary distance scale. Currently, the calibration accuracy of the zero point of the distance scale is about 10%. With the advent of long-baseline interferometers operating in the optical and infrared a new opportunity appears to improve the accuracy of the Cepheid distance scale using the Baade–Wesselink (BW) techniques (Sasselov and Karovska 1994). A precise interferometric measurement of the change of the angular radius of a Cepheid, combined with the radial displacement computed from the Cepheid's integrated radial-velocity curve, will allow a direct and very accurate distance determination.

Measurements of mean diameters of several Cepheid variables of less than a few mas are now being carried out using several long-baseline interferometers including the GI2T (Murrard 1997) and NPOI (Nordgren *et al* 1999). Currently, the diameter measurements are made using uniform brightness distribution on the stellar disk. However, Sasselov and Karovska (1994) showed that the differences in model brightness distributions have

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

significant effects on the interferometric angular size measurements of Cepheids. They demonstrated that using a uniform brightness distribution will lead to an underestimate of the size of the Cepheid of up to 40% in the continuum and an overestimate of approximately 25% in the strong lines due to high level of scattering above the limb and sensitivity to local dynamic disturbances (shock waves, velocity gradients, etc).

With the ongoing development of very-long-baseline (more than 100 m) stellar interferometers it will soon be possible to measure the small changes of the angular radius as a function of the pulsation process of many galactic Cepheids (see Davis 1994). A combination of accurate interferometric diameter measurements using model-predicted center-to-limb brightness distributions will provide a new venue for determining Cepheid distances via the Baade–Wesselink method (Sasselov and Karovska 1994) and a reliable zero point of the Cepheid distance scale.

Indirect diameter measurement methods

In addition to direct measurements of angular diameters there are several indirect methods that provide measurements of stellar diameters. In the following we highlight these methods.

Eclipsing binaries

Traditionally the most common source of stellar diameters, detached ECLIPSING BINARIES still offer one of the most precise means to measure stellar diameters today. The analysis of their light curves yields complete orbital elements of the binary system, including accurate relative radii. The diameters of the two stars in units of the orbital radius can be determined from the duration of the eclipses provided that all four contacts are well observed (figure 2). If in addition we can also measure the radial velocities of the two stars, we can express their radii in linear units. Such precious double-lined detached eclipsing binaries are very rare. Roughly 45 systems are known and they provide the most accurate (at 1% level) stellar radii in astronomy (Andersen 1991). The binaries in the sample include very massive (O stars), as well as a couple of low-mass stars (M1 V), mostly on the main sequence. Unfortunately, only two red giants are represented. The average mean error of the stellar radii is 1.5%, the best being EK Cep A (0.35%). The main difficulty in determining individual radii for stars in many eclipsing binaries is that the computed light curves may be nearly identical for a wide range of geometric configurations. This does not occur when eclipses are total (or nearly so). Values from partially eclipsing systems should not be trusted to an accuracy of 1–2% unless verified by detailed spectroscopic evidence. Only one such binary system has been studied outside our Galaxy—HV2274 in the Large Magellanic Cloud—and accurate radii derived (Guinan *et al* 1998).

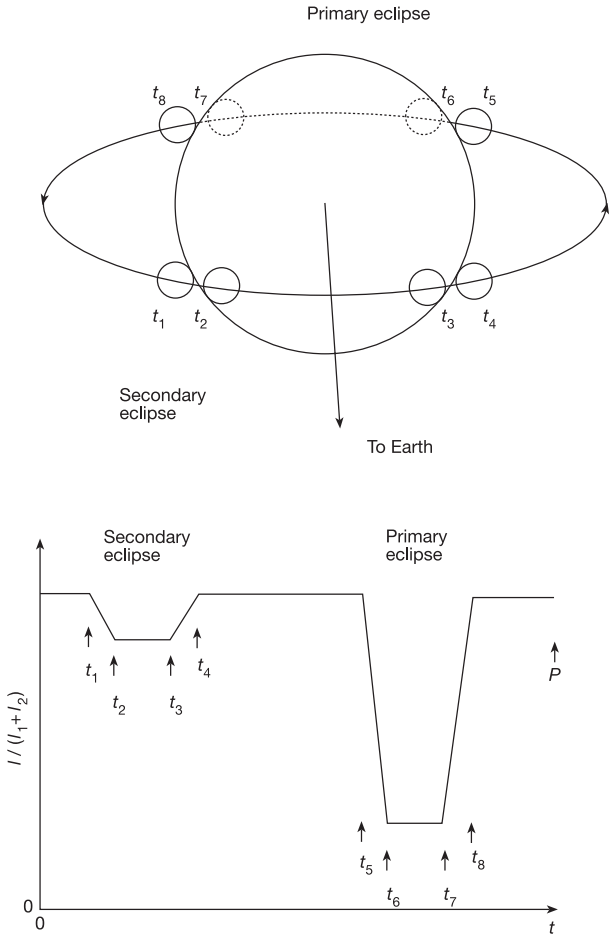

Figure 2. If the orbital plane of a binary happens to be nearly edge-on as seen from the Earth, then ecilpses will occur as one of the components passes in front of the other. The eclipse geometry is shown above, and a schematic light curve for the case in which the smaller star has the greater surface brightness is shown below. The binary period is P.

Stellar radii and the Stefan–Boltzmann law

A traditional and basic, but not very accurate, indirect method of measuring a stellar radius is using the definition of stellar effective temperature in terms of the Stefan–Boltzmann law,

$$L = 4\pi R^2 \sigma T_{\rm eff}^4$$

$$\sigma = 5.6 \times 10^{-8}\ {\rm J\ s^{-1}\ m^{-2}\ K^{-4}}$$

where the assumption is that of a star as a blackbody sphere. With a temperature derived from the stellar spectrum or multicolor photometry, and a luminosity inferred from the apparent brightness of the star and its distance, the stellar radius is determined. The apparent brightness is evaluated from the apparent magnitude measured at the Earth and the distance can be estimated using the parallax measurements or other indirect methods.

A refinement of this method is the infrared flux method (Blackwell and Lynas-Grey 1994) to derive stellar angular diameters and effective temperatures by measuring the monochromatic flux at an infrared frequency and the bolometric flux and using theoretical model atmospheres to estimate the flux at the star's surface. With distances, e.g. from PARALLAXES, the angular diameters thus obtained can be converted to absolute diameters. In a different approach, one could employ theoretical models of STELLAR EVOLUTION, and combined with distances (and for some types of stars) these can provide stellar radii estimates as well.

The accuracy of these techniques is not very high (10–15%) and depends strongly on the type of star involved. For stars similar to the Sun, the accuracy in determining their radii could be as high as 6%.

Baade–Wesselink techniques

Doppler shifts of spectral lines originating in moving photospheres may be used to derive absolute stellar diameters, e.g. in radially pulsating variable stars and expanding supernova ejecta. The method relies on a combination of kinematic and thermodynamic relations and works very well for pulsating stars such as Cepheids and RR Lyrae (or any stellar surface in radial motion). It is generally called the Baade–Wesselink method (Gautschy 1987). The method is based on the idea that an emitting surface in radial motion can be observed directly *and* simultaneously through the Doppler shift in the spectra as well as in flux and temperature variation. The Doppler shifts provide radial velocities, which, when integrated over a certain time (or cycle), yield the linear displacements of the moving stellar surface, ΔR. The flux and temperature variation yield the ratio of the radii of the stellar surface at different times, through the use of the expression for the stellar luminosity, L, and the definition of effective temperature, $T_{\rm eff}$ ($L = 4\pi R^2 \sigma T_{\rm eff}^4$). This approach constitutes the classical application of the BW method to Cepheids (Baade 1926), where for phase pairs of equal color (assumed $T_{\rm eff}(2) = T_{\rm eff}(1)$) we obtain

$$\left[\frac{R(2)}{R(1)}\right]^2 = \frac{L(2)}{L(1)} = 10^{-0.2(m_2 - m_1)} \qquad (1)$$

where m_i is the stellar magnitude. Calculating these ratios and integrating the radial-velocity curve of a Cepheid over its entire pulsation cycle then can give us the mean linear radius of the star. The method has the potential to obtain 3% accuracy, although this potential has not yet been realized.

Gravitational microlensing

The gravitational lensing of a star's light by another distant (point-like) star is called MICROLENSING and can provide a direct measurement of the diameter of the lensed star. When the lensing star transits across the face of the lensed star, the ratio of the angular impact parameter to the angular radius of the lensed star is determined from the shape of the photometric light curve. In this case an astrometric measurement of the Einstein ring radius (with precision of 10 μas) can give the angular diameter of the lensed star with very high precision (1%). Such events are not common but have already been observed (MACHO 95-30). More common are microlensing events in which the lens is a binary star, with caustic crossing the face of the lensed star. Given precise astrometry, accurate diameters can be derived in these events (Paczynski 1998).

Degenerate stars and black holes

The diameters of WHITE DWARFS, NEUTRON STARS and BLACK HOLES are poorly known. The majority of estimates are based on theoretical models and there is very little input from observational data. Combining luminosities with effective temperatures is the most common approach to deriving white dwarf radii. Photometry (color and flux) and model atmospheres allow an estimate of the radiation flux at the white dwarf's surface. With a distance from parallaxes (more than 100 white dwarfs have accurate ones), the radius can be determined. A different approach is afforded by the high gravity at the surface of white dwarfs which is responsible for large gravitational REDSHIFTS (up to 90 km s^{-1}). These redshifts can be measured accurately for a few white dwarfs in detached binary systems, in which the white dwarfs' masses are very well determined. As a result accurate radii for the white dwarfs can be estimated (Lang 1992). An example is Sirius B with $R = (0.0078 \pm 0.0002) R_\odot$. Typical white dwarf radii have a very narrow range around $0.01 R_\odot$.

For neutron stars and black holes certain constraints on their diameters can be placed if they happen to be in accreting binary systems with normal stars as companions. Neutron stars in such systems are often the source of x-ray emission, which is often variable and exhibits bursts. Strong x-ray bursts show photospheric radius expansion which can be used to derive the radius if time-resolved spectra are obtained (Damen *et al* 1990). An alternative method relies on high-resolution x-ray spectroscopy and spectral line broadening (Paerels 1997), much like the traditional technique used in stellar spectroscopy. The latter should become available with x-ray telescopes such as CHANDRA and XMM. In all these techniques the knowledge of the neutron star radius is strongly dependent of the mass estimate. This is especially true in the case of black holes in such binary systems (Menou *et al* 1999). Current estimates of neutron star radii (e.g. Golden and Shearer 1999) are in the theoretically expected range 8–10 km.

Stellar Distributions

Our Galaxy is a collection of stars moving in orbits through the Galaxy's gravitational field (see GALAXY: STRUCTURE). A 'stellar distribution' is a description of the distribution (in real space and in velocity space) of the stars in our Galaxy. Different kinds of stars have different distributions. A knowledge of the distribution of stars, obtained from counts of stars of many kinds, leads to an understanding of the structure and dynamics of groups of stars in general and to a description of our Milky Way Galaxy in particular. It also leads to interesting conclusions about the origin and history of our Galaxy.

Censuses of stars began some two centuries ago with star counts; that is, numbers of stars at each discernible level of apparent brightness. It is easy to see that fewer bright stars are seen than fainter ones; with each fainter magnitude the number of visible stars triples. However, what are the reasons and to what faintness does this observation extend? In the 20th century, after it had been discovered that stars vary greatly in both intrinsic brightness and distance, distance estimates of large numbers were needed in order to distinguish between the stars that happened to be near our solar system and the truly luminous stars and to distinguish the faint cut-off in star numbers, because a minimum brightness to stars is known to exist and because the Galaxy stops at a certain distance from us.

Stellar properties such as brightness, color and distance must be carefully evaluated for many thousands of stars for this separation to be made with precision. From such data, and from stellar motions, one can derive the underlying structure and dynamics of our Galaxy. An understanding of stellar distribution and galactic structure therefore requires the accurate determination of these stellar parameters for all of the principal star types: the main sequence or dwarf stars, the giants and the supergiants and, lately, the faint sub-main-sequence brown dwarfs as well.

Background

In 1543, Copernicus proposed and published the concept that the Sun rather than the Earth lay at the center of the solar system. Soon thereafter, as his heliocentric system gained adherents, it became accepted that the stars were not just beyond Saturn, then the farthest known planet, but were many many times its distance from the Sun, for they showed no observable parallax as they must if the Earth moves.

Research into stars and their distribution in space remained dormant until Sir William Herschel, discoverer of Uranus in 1781, initiated the study of their arrangement. Herschel made systematic and extensive counts of stars by magnitude and found that their density in space decreased in all directions with distance from the solar system. Along the plane of the Milky Way the decline was gradual, but in the perpendicular directions it was more precipitate. He was led to a model of the distribution of stars as a disk—a grindstone-shaped universe of stars with the Sun near its center.

The 19th century saw little progress in this field, but it witnessed the development of photography, spectroscopy and other tools that would later be used to expand the field of stellar astronomy. Above all was the successful measurement of the first stellar parallaxes in 1838 and distances to the stars became known directly from these heliocentric parallaxes. This stellar motion, reflecting the orbital motion of the Earth about the Sun and constituting proof of that motion, had been sought by Aristotle and many others since. Only after 1838 could distances to stars be individually assigned. With parallax and proper motion (the apparent angular motion of a star across the sky) the true stellar motion could be derived and galactic dynamics could begin. By the end of the 19th century parallaxes were known for about 70 stars. (See PARALLAXES.)

Around 1900, the Dutch pioneer J C Kapteyn initiated the modern period of the study of stars and their distribution in space. Concurrently, Frank Schlesinger at the Yerkes Observatory introduced photography into astrometry and quickly increased the number of known parallaxes to over a thousand. Shortly before World War I, E Hertzsprung and H N Russell used these many hundreds of new parallaxes to discover the characteristics of the distribution of stars by surface temperature (as deduced from spectral type or color) and intrinsic luminosity. Their representation of this distribution is now called the Hertzsprung–Russell (HR) diagram, or in a more common form, the color–magnitude (CM) diagram. The astrophysics of its features was not explained for many years, but the main sequence and the giant and supergiant domains gave form to further stellar study and classification. In whichever form, the diagram represents a plot of intrinsic luminosity of stars versus their surface temperatures; it and the loci of the major star groupings are shown in figure 1.

One of the features that arose in the wake of this diagram was the stellar luminosity function, the frequency distribution of stars ordered by intrinsic brightness (absolute magnitude). It became possible to give a quantitative description of the distribution of star luminosities as they really are, as an aid in deducing spatial distribution of stars from their observed distribution. Surveys were created that distinguished the nearby fainter stars by their proper motion from their numerous distant and brighter counterparts. A quantitative description of the distribution of nearby stars in space could be provided as an aid in deducing the distribution of star luminosities from their observed distribution. Clearly these two developments have to meet in a consistent picture of the distribution of stars.

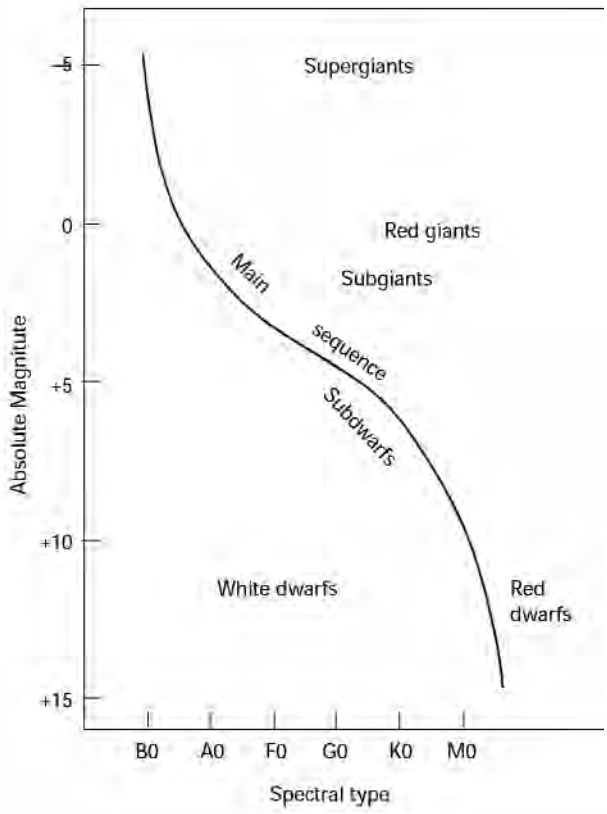

Figure 1. The HR diagram shown schematically. The regions inhabited by the main sequence stars (normal dwarfs), giants and supergiants are shown. (Upgren A R 1998 *Night has a Thousand Eyes: A Naked-Eye Guide to the Sky, its Science and Lore* (New York: Plenum))

The first of these developments resulted from the studies at Leiden by Kapteyn, P J van Rhijn and their associates and the second was due to W J Luyten among others. These astronomers realized that apparent magnitudes and proper motions could be determined for stars by the thousands. It is worth noting that, until very recently, these were the only properties known for the majority of even the nearest stellar neighbors. In fact, their faster proper motion became the single stellar parameter by which most faint nearby stars could be recognized as such.

Astrometric surveys based only on apparent brightness and proper motion were known even then to be fraught with biases and systematic errors, but for the middle third of the 20th century they formed the observational data for the distribution of stars in space. Much ingenuity was demonstrated in the avoidance of the worst pitfalls due to incomplete counts of even the nearest stars. It was recognized that, for a full understanding of stellar distribution, the three spatial coordinates and their three first derivatives with time must be well known for every kind of star. Expressed in a coordinate system of a radial (or line-of-sight) direction and two transverse directions (the two orthogonal axes in the tangent plane of the sky at the position of the star), all but one of the six derive from the equations of condition for stellar motion. The distance is set by the parallax with the direction cosines appropriate for the star's position in the sky, and the two mutually orthogonal transverse velocities, $T(x)$ and $T(y)$, are derived from the proper motion in each of the two directions divided by the parallax. Only R, the velocity in the radial direction, remained to be found. The problem then was that this radial velocity could only be obtained for bright stars, and the distances and transverse velocities were only available for nearby stars. Far too few stars made both lists for an accurate picture of stellar distributions and motions to be made.

Recent results

The last few decades have been a time of rapidly improving stellar samples and a more faithful representation of the stars in general. Photoelectric photometry, which allows stellar brightnesses to be measured with high precision, has become an alternative method of establishing a star's approximate distance, with greater rapidity and extended to more distant stars than the measurement of stellar parallax could achieve. Together with the stellar spectrograph, photometry is able in most cases to locate a star's proper position on the HR diagram and thus its distance. Larger telescopes with more sensitive equipment have extended star counts to much fainter stars. The newer surveys have been active particularly in the infrared spectral regions, where the faintest stars are more visible.

Although several thousand stars had parallaxes by 1989, only a minority of them had parallaxes sufficiently larger than their errors to be of any real value in setting an adequate distance scale. Then, in that year the European Space Agency launched Hipparcos, a satellite devoted to positions, parallaxes, and proper motions. The mission was first conceived by Pierre Lacroute and the acronym stands for 'high precision parallax collecting satellite'. The name also honors Hipparchus, the astronomer who first catalogued the stars and their brightnesses and positions in the 2nd century BC. On completion of the mission about 1993, it delivered parallaxes and proper motions of almost 120 000 stars; most of the data were enough larger than their errors for galactic research. Hipparcos allowed the precise calibration of the luminosities of all but the intrinsically brightest stars. Only the supergiants, Cepheid variables and their like do not yet have reliable luminosities from their individual parallaxes because even the closest among them are still too far away.

Hipparcos, the Hubble Space Telescope launched by NASA at about the same time and other large ground-based telescopes have revolutionized the field, having

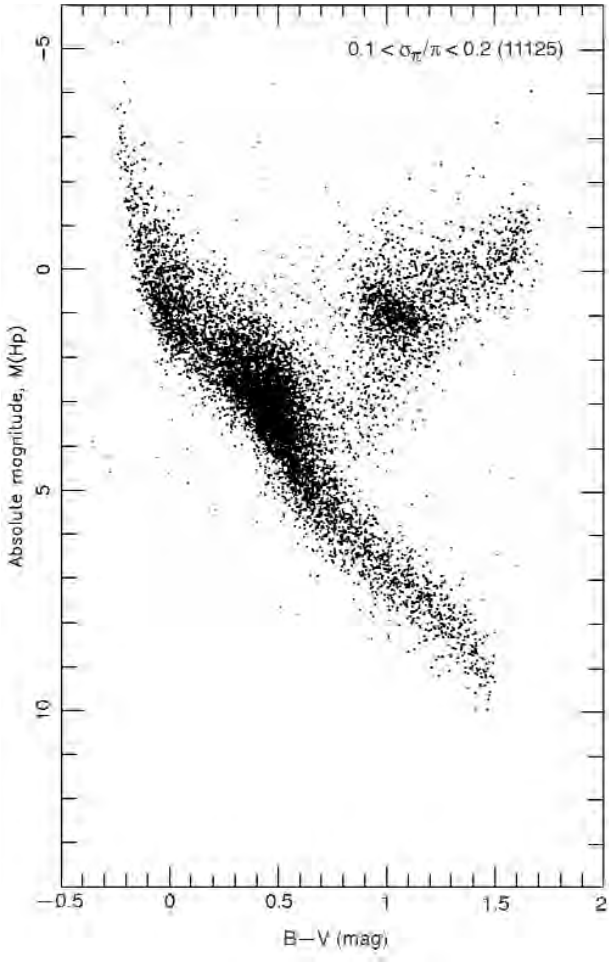

Figure 2. The CM diagram for 10 793 stars with accurate parallaxes determined by the Hipparcos satellite. Notice the main sequence and giant regions. Only one supergiant (Canopus) is close enough for a good parallax. (Perryman M A C *et al* 1995 Parallaxes and the Hertzsprung–Russell diagram from the preliminary Hipparcos solution H30 *Astron. Astrophys.* **304**, 69–81)

provided the means for surveys, particularly in the infrared, where the faint stars and brown dwarfs are most detectable. The potential from the data in the final catalogue of Hipparcos results is not yet likely to be fully exhausted.

Two programs, now in the planning stage, will further greatly improve the precision in stellar distances and motions. Both make use of large telescopes in space and interferometric techniques and, if successful, can achieve errors as low as a microsecond. They could then produce a reliable parallax for almost every resolvable object in our Galaxy as well as some in the Magellanic Clouds. One of these is GAIA (Global Astrometry Instrument for Astrophysics), a program of the European Space Agency and named for a goddess of the Earth. Another is known as SIM (Space Interferometry Mission), an American program. At last notice, both efforts are a decade or more away from launch. In the just-published second edition of his book, Modern Astrometry, Professor Jean Kovalevsky outlines in detail Hipparcos, as well as these and other future projects vital to the further understanding of the arrangement of stars.

Figure 2 shows a CM diagram for several thousand stars plotted from Hipparcos data of high precision. We see that the majority of stars form a sequence extending from the upper left (hot and bright) to the lower right (cool and faint). This is the main sequence, and it is now known to represent a sequence in the masses of stars as well as their luminosities. The sequence extending from it to the right near the center of this main sequence is known as the giant branch, and the few stars in the lower left (hot and faint) are the degenerate stars or white dwarf stars. Just above the top of the figure would be the supergiants, the brightest of all stars (see figure 1 for a schematic representation). The features of the CM diagram must be inferred from a large amount of data.

Current models of stellar distribution

A broad picture of stellar distributions emerged early in the 20th century and has been substantiated in its basic features and improved by more recent observations. Star counts made in all directions reveal that the one or two thousand brightest stars, those readily visible to the naked eye, maintain a reasonably uniform distribution all around the sky. The luminous stars of the Milky Way delineate its plane, seen edge on from within, of our great spiral Galaxy. They thin out very rapidly with angular distance from this plane, represented by a great circle called the Galactic Equator centered within the visible Milky Way. Distant stars are relatively rare anywhere near the directions perpendicular to the Equator, known as the Galactic Poles. The major component of the Milky Way is thus a great disk some 100 000 light-years or more in diameter but only a few hundred to a thousand light-years in thickness. The disk is centered on a much denser core or nucleus and is surrounded by the thinly populated galactic halo.

Stars fall into two or more main groups or populations, with fundamental differences between them in their chemical constitution and location in the Galaxy. The primary difference is one of age; that is, time since formation. The globular clusters and a few other stars form a nearly spherical halo about the disk and contain the oldest stars, whereas the younger stars are more confined to the disk region. Recent work indicates the presence of a division within the disk population into young 'thin-disk' stars and an older middle-aged group, the 'thick-disk' stars. Each group is distributed roughly normally about the plane along the perpendicular or z-axis direction. The dispersions of the groups are not precisely known and are found to differ from one investigation to another, but are of the order of 100–200 pc for the thin

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

disk and 500–1000 pc for the thick disk. The very old 'halo' population is more nearly spherically distributed with a dispersion in z of several thousand parsecs.

Within the thin-disk population, some evidence suggests fine structure in the form of 'moving groups' of stars, not unlike widely extended open star clusters and possibly spawned by those that have dissipated into the general stellar background. Such star streams range from the proven (the closest of which is the so-called Ursa Major or Sirius moving group, counting among its brighter members Sirius and most of the stars forming the Big Dipper (or Plough)) to the very tentative. The number of groups and their percentage of the total stellar population are not yet known. Galactic dynamics indicates that stars older than about a billion years are well mixed and would show little star streaming or other preferential motion.

Distributions in surface temperature, luminosity and metal abundance

It is now widely recognized that stars vary over a great range in three distinct parameters: luminosity, surface temperature and an age-related parameter measured by the abundance of metals in their atmospheres. This is one of the outstanding achievements in galactic structure and kinematics of recent years. After distances became known through the parallax process, the variation due to distance could be removed from consideration and some order could be made among the kinds of stars we really see. In recent decades, the nature of stars was made clear by means of plots of their spectral types against their intrinsic luminosities (absolute magnitudes) in the HR and CM diagrams. Because the spectral type was found to correlate with the colors of stars, both diagrams measure the basic stellar properties of surface temperature and luminosity. The two properties depend overwhelmingly on the star's initial mass. Recently the third dimension related to chemical composition has been well surveyed. We have found that the commonest measure of chemical composition is the abundance of metals present. We know that the Milky Way has become enriched in metals from its early days when almost all matter was in the form of hydrogen. As stars evolved and died, the metals produced in their cores dissipated throughout the system and now amount to about 3% of younger stars by mass. In its early days the Milky Way collapsed from a near-sphere onto a disk, much as did the matter in the solar system later on. Correlations were discovered between the age of a star, its metal content and its galactic orbit. The metal-poor stars were formed first when the Galaxy was more nearly spherical and the others came along much later.

The main sequence contains the great majority of stars, and we now know that all stars start out on the main sequence in a location determined by stellar mass. The giants and supergiants have experienced major changes in their interiors, which cause them to become cooler and brighter; thus, they have become much larger in diameter and of reddish appearance. The main sequence stage accounts for most of a star's total lifetime and, since more massive stars are far more luminous than smaller dwarfs, they exhaust their energy and pass through this stage much more quickly. The thermonuclear fusion processes by which hydrogen is converted into helium and energy at and near the core is the source of energy that drives the star during this stage. Supergiants last only for a few million years, whereas the red dwarfs forming the lower main sequence can endure for tens of billions of years, longer than the age of the Galaxy. We have a picture of the stars not unlike a single snapshot of a forest, from which we must infer the types of trees and shrubs, and, from saplings and mature plants, the growth and life cycle of each species.

A star is a furnace composed of its own fuel. In the interiors of massive bright stars the energy derives from their convective cores passing up through radiative envelopes. In intermediate-mass stars such as the Sun, the two means of energy transport are reversed, with the energy passing outward from a radiative core through the outer layers forming the surrounding envelope via convection. As we descend in mass farther down the main sequence, we encounter the faint red dwarf stars, the predominant stellar component of the galaxy and presumably the universe. Energy transport in stars below 0.3 solar masses seems to be fully convective. All such small stars ever formed are still alive, since their energy exhaustion rate is low. At about 0.08 solar masses, we reach the limit below which the central temperature does not reach the point at which the fusion of hydrogen into helium can begin, and the star cools off after a short period of luminescence through gravitational contraction to become a brown dwarf. The procession on down in mass from 0.08 to 0.001 solar masses brings us to the mass of Jupiter, our largest planet.

In the last few years with larger telescopes and subtler ancillary photosensors now available, astronomers have delved into these less massive objects in the galaxy. Ten years ago we knew of no object outside the solar system less massive than a full-fledged star, defined as an object with fusion going on in its core. In order for this to take place, a central temperature of at least three million kelvins must be maintained. Because core temperatures of stars rise with gravitational pressure, which in turn rises with stellar mass, stars as they contract from interstellar material must be above a minimal mass in order for the thermonuclear fusion, the conversion of hydrogen into helium plus energy, to begin.

Less massive stars, these almost-stars, are now known as brown dwarfs despite their red color, since the term 'red dwarfs' has been reserved for the faintest stars

that do shine by fusion processes. Brown dwarf stars were presumed to exist for some time, but their confirmation came only in the last few years with improved sky surveys. Curiously, planets orbiting other stars were also proven to exist at about the same time. Through gravitational perturbations affecting nearby stars, we are now aware of planets within an order of mass of Jupiter orbiting other stars; that is, masses from about one-half to about ten times the mass of Jupiter, far smaller than the brown dwarfs. Jupiter-sized masses have been detected around some 50 stars similar to the Sun since 1995. Jupiter and these other planets never were and never will be stars. However, they are now a part of a continuous distribution in mass of the common objects in our galaxy, and their abundance has become a matter of interest for the future. This is because smaller brown dwarfs have been found that are only a little more massive than the largest extrasolar planets, and soon the final gap in mass may be filled in, thus providing a continuity in mass from the smallest debris in the solar system to the mightiest of stars.

It is yet too early to know with any certainty the space density of brown dwarfs or of planets. A recent estimate places the number of main sequence stars of spectral classes F, G and K (between about 0.5 and 1.5 solar masses) with one or more planets at about 7% of their total number. The planets we have detected are of the size of Jupiter and Saturn, but it is widely assumed that Earth-sized planets are also present in large numbers and that we may be able to discover some of them in the next decade.

Metallicity in stars

With the recent advent of the measurement of metallicity—the quantity of elements heavier than helium—in stars, we are able to put together a much more coherent picture of the stars and the development of the Galaxy. To an astrophysicist, the term 'metals' includes all elements except the lightest two, hydrogen and helium, but in fact only carbon, nitrogen, oxygen, iron and a few in between have noteworthy abundances. Elements heavier than iron are found only in trace quantities if at all.

The abundance is defined by the ratio between a star and the Sun of the percentage of metals, sometimes specifically limited to iron alone, compared with hydrogen (which is known to account for the great majority of stellar material) and is specified as [M/H] where

$$[\mathrm{M/H}] = \log[(\mathrm{M/H})_{\mathrm{star}}/(\mathrm{M/H})_{\mathrm{sun}}]$$

or, in the case of iron alone,

$$[\mathrm{Fe/H}] = \log[(\mathrm{Fe/H})_{\mathrm{star}}/(\mathrm{Fe/H})_{\mathrm{sun}}]$$

The Sun is a rather young metal-rich star, and others with the same chemical composition will show [Fe/H] near zero. Old stars such as those in globular clusters reveal [Fe/H] to be near –2; that is, iron is down by a factor of 100 compared with its relative abundance in the Sun. Stars of intermediate age lie near –1 (one-tenth the solar iron abundance). Although the parameter has not been extended to enough stars to properly map the prevalence of metals (iron) throughout the Galaxy, or even the solar neighborhood, studies made in connection with the kinematics of stars have revealed a calibration of stellar populations into two or, more likely, three stellar populations. The first group is comparatively rich in metals ([Fe/H] near zero, the solar abundance) and is associated with the thin disk, extending to only a few hundred parsecs on either side of the galactic plane. The second group, corresponding to the thick disk, is of intermediate age and has a metallicity near –1, with faster motions perpendicular to the plane in the so-called z direction, and thus they carry to about a kiloparsec above and below the plane. The reality of this thick disc is still in some doubt—the evidence is strong, if not yet conclusive.

The oldest stars are of metallicity –2 or less and form the galactic spheroid or halo. They consist of globular clusters and their component stars, along with a few old field stars, and fill a nearly spherical region with a diameter equal to the disk and a thickness above and below it of several kiloparsecs. In the plane, the halo stars make up less than 1% of the total, and the intermediate stars about one-quarter of the total. We find that the metal-rich stars move slowly in the z direction, with an average velocity of 12 km s^{-1} at the plane ($z = 0$), so that they move to only one or two hundred parsecs above and below the plane before the gravitation of the material in the plane pulls them back into it. The intermediate stars average near 30 km s^{-1}, so that with increasing z distance they take over. Then come the halo stars, which become the majority in regions more than 1 kpc from the plane.

Stellar samples and their biases today

With the newer generation of large telescopes and charge-coupled devices and other detectors of advanced sensitivity, we are now aware that stars do not keep tripling with each additional fainter magnitude forever. At a magnitude of about 12, about the faintest magnitude visible in a telescope of aperture 6 in, the newer data show that fainter stars fall off more rapidly. At some point this must occur, since our Galaxy is not infinite. Its several hundred billion stars must run out at some point. Work has also been done to improve the stellar luminosity function, both as to its fainter end and with regard to the relative space densities of the brown dwarfs. Since the brown dwarfs shine for only a limited time before going dark, the abundance of visible and no-longer visible brown dwarfs is unknown and may be quite large.

The stellar population increases markedly with faintness along the main sequence. The faint red dwarfs dominate the stellar component in mass, although not in luminosity. Each brilliant supergiant may be a billion times as luminous as a faint dwarf, even if millions of times less numerous. Since most of the stellar mass is in the form of small red stars and possibly also brown dwarfs—including those that no longer shine—it becomes very important to know just how many there are in a given volume of space. Such information is vital to any study of the mass distribution and dynamics within our Galaxy. Selection effects abound in this effort, since identifying dwarfs from the many background stars that appear just as faint because of their greater distance involves detection by proper motion or by spectral or color characteristics. Now that surveys singling out the faint stars are not limited to astrometric means, and also extend from the visible spectral region into the infrared, this work is proceeding apace.

The determination of an accurate stellar luminosity function requires care in both the observations and the underlying theories and the story of stellar distribution is largely one of ever-improving observational techniques and statistical analyses applied to ever-increasing numbers of stars of all kinds. At this time, the census of stars is known very accurately only to a distance of about 5 parsecs (about 16.3 light years) from the Sun. Table 1 lists the number of stellar systems and of individual stars known to be within that distance as a function of the year of publication of a reference to those data. Note that the numbers of known stars are always increasing over time but appear to be nearing a constant. Any extension of the distance beyond 5 parsecs quickly shows a decline in space density, first for the faintest red dwarfs, but then for stars of ever-increasing luminosity.

Table 1. The numbers of stars known within 5 pc of the Sun.

Year of publication	*Number of stars*	*Number of systems*
1945	48	37
1957	56	42
1974	60	45
1981	63	47
1987	65	50
1993	67	51

Stars and the dynamics of the Galaxy

Half a century ago, it became clear that the disk of our Galaxy is not homogeneous throughout its extent, but rather resembles many other large galaxies in possessing a spiral structure, and lately possibly a barred structure as well. Objects known to be very young include the supergiants, especially the blue ones at the very top of the main sequence, the Cepheids and the HII regions or emission nebulae. These were the objects found to delineate spiral arms in other galaxies, and studies of their distribution in this one confirmed the presence of spiral arms here. When we consider the loci of even moderately older stars, such as the main sequence A stars like Vega and Sirius, the arms are no longer recognizable among the background stars. Star formation regions lie along the arms, but the stars produced gradually drift away and diffuse throughout the disk between the arms.

The total mass density of all matter is a number of great significance. Galactic dynamics depends on the mass distribution within the Galaxy as a function of location. J H Oort showed that the distribution of motions of stars in the direction normal to the galactic plane is governed by the total mass density from all matter in the galactic plane in the general region near the Sun. Stellar motions here and at some distance from the plane are not known with high precision, but they indicate a mass density of between 0.15 and 0.18 solar masses per cubic parsec. This number is now called the Oort limit. The observed mass density in the region of the Sun summed up over all known stars and interstellar material does not seem to reach the Oort limit. It may be about 0.10 solar masses per cubic parsec, with the interstellar gas and dust accounting for one-third to one-half of the total. The rest, the so-called missing mass, is presumed to exist in the form of dark matter. None of these numbers is of sufficiently high accuracy to settle the problem to the desired degree for the best galactic dynamical theory. This confirms the need to press on for ever more dependable stellar censuses, especially near the Sun, where we have some chance of achieving completeness.

Future developments

Future developments in our understanding of stellar distributions will require both an increasing number and precision of observations. However, many of the problems that remain arise from the fact that radial velocities and metal abundances are still only known for a handful of stars. Is there a gradient in metallicity across the galactic disk or outward from its center or in the direction perpendicular to the plane as some have found? How many discrete stellar populations are there, and do they represent distinct waves or bursts of past star formation or a continuity in age-related stellar properties?

For the lack of radial velocities as much as any other data, we lack space motions. Without precise quantitative measures of the equivalent widths of spectral lines and related observations, we lack metal-to-hydrogen ratios. These quantities are ineluctably closely correlated, but how? Despite improvements in theory, the solution of these problems will require programs dedicated to observations of many common nearby objects. It is possible that the search for stars with planetary systems of

various kinds will stimulate a new wave of observations of this type.

Stellar Dynamics

Stellar dynamics describes systems of many point mass particles whose mutual gravitational interactions determine their orbits. These particles are usually taken to represent stars in small GALAXY CLUSTERS with about 10^2–10^3 members, or in larger GLOBULAR CLUSTERS with 10^4–10^6 members or in GALACTIC NUCLEI with up to about 10^9 members or in galaxies containing as many as 10^{12} stars. Under certain conditions, stellar dynamics can also describe the motions of galaxies in clusters, and even the general clustering of galaxies throughout the universe itself. This last case is known as the cosmological many-body problem.

The essential physical feature of all these examples is that each particle (whether it represents a star or an entire galaxy) contributes importantly to the overall gravitational field. In this way, the subject differs from CELESTIAL MECHANICS where the gravitational force of a massive planet or star dominates its satellite orbits. Stellar dynamical orbits are generally much more irregular and chaotic than those of celestial mechanical systems.

Consequently, the description of stellar dynamical systems is usually concerned with the statistical properties of many orbits rather than with the detailed positions and velocities of an individual orbit. Thus it is not surprising that the KINETIC THEORY OF GASES developed by MAXWELL, Boltzmann and others in the late 19th century was adapted by astrophysicists such as Jeans to stellar dynamics in the early 20th century. Subsequent results in stellar dynamics contributed to the first analyses of kinetic plasma physics in the 1950s. Then rapid evolution of plasma theory in the second half of the 20th century, stimulated partly by prospects of controlled thermonuclear fusion, in turn contributed to stellar dynamics. This was an especially productive interdisciplinary interaction.

After describing basic physical processes such as timescales, relaxation processes, dynamical friction and damping, this article derives the virial theorem and mentions some applications, discusses distribution functions and their evolution through the collisionless Boltzmann equation and the BBGKY hierarchy, and outlines the thermodynamic descriptions of finite and infinite gravitating systems. The emphasis here is on fundamental physics rather than on detailed models.

Basic ideas

We start with simple ideas that are common to most stellar dynamical systems. For point masses to represent their components, physical collisions must be rare. In a system of objects, each with radius d, this means that the total internal volume of all the objects must be much less than the volume over which they swarm. Two spherical objects of radius d will have an effective radius $2d$ for a grazing collision whose cross section is therefore $\sigma = 4\pi d^2$. If there is a number density n of these objects and they move on random orbits, their mean free path to geometric collisions is

$$\lambda_G \approx 1/n\sigma \approx \frac{R^3}{3Nd^3}d \qquad (1)$$

where R is the radius of a spherical system containing N objects distributed approximately uniformly.

This has two easy physical interpretations. First, the average number of times an object can move through its own diameter before colliding is essentially the ratio of the cluster's volume to that occupied by all the stars. Second, the number of cluster radii the object can traverse before colliding is essentially the ratio of the projected area of the cluster to that of all the objects. In many astronomical systems, these ratios are very large. As examples, 10^5 stars in a globular cluster of 10 pc radius have $\lambda_G/R \approx 3 \times 10^{11}$ and 10^3 galaxies in a cluster of 3 Mpc radius have $\lambda_G/R \approx 30$. Therefore stellar dynamics is a good approximation over a wide range of conditions. It may, however, break down in the cores of realistic systems where only a few objects dominate at the very center and orbits are more regular.

Although geometric collisions may be infrequent, gravitational encounters are common. These occur when one object passes by another, perturbing both orbits. Naturally, in a finite system all the objects are passing by each other all the time, so this process is continuous. In a system which is already fairly stable, most perturbations are small. However, their cumulative effects over long times can be large and affect the evolution of the system significantly. To see how this works, we introduce the fundamental notion of a 'stellar dynamical relaxation time'. This is essentially the timescale for a dynamical quantity such as a particle's velocity to change by an amount approximately equal to its original value.

As an illustration of the general principle, consider two-body relaxation. Suppose, as in figure 1, that a massive star m_1, deflects a much less massive star m_2. Initially, m_2 moves with velocity v perpendicular to the distance b (the impact parameter) at which the undeflected orbit would be closest to m_1.

There is a gravitational acceleration Gm_1b^{-2} which acts for an effective time $2bv^{-1}$ and produces a component

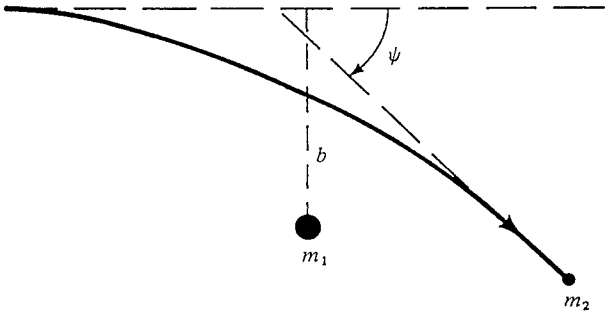

Figure 1. The deflection of a star m_2 by a more massive star m_1, schematically illustrating two-body relaxation.

of velocity

$$\Delta v \approx \frac{2Gm_1}{bv} \tag{2}$$

approximately perpendicular to the initial velocity. Since $\Delta v \ll v$, the effects are linear and they give a scattering angle $\psi \approx \Delta v/v$. A more exact version follows the orbits in detail, but this is its physical essence. It shows that large individual velocity changes, $\Delta v \approx v$, and large scattering angles occur when two objects are so close that the gravitational potential energy, Gm_1m_2/b, approximately equals the kinetic energy, $m_2v^2/2$. Such close encounters are rare. Typical encounters in a spherical system of total mass M and radius R containing N objects have an impact parameter about equal to the mean separation, $b \approx RN^{-1/3}$. The average mass $m_1 \approx M/N$, and the initial velocity is given by the approximate balance of the system's total kinetic and potential energy, $v^2 \approx GM/R$. (This last relation follows from the virial theorem below.) Therefore from equation (2)

$$\frac{\Delta v}{v} \approx \psi \approx N^{-2/3} \tag{3}$$

for $N \gg 1$, and most gravitational encounters involve little energy or momentum exchange. Exceptions may occur in the centers of clusters, particularly among more massive particles, where the core is relatively isolated and the effective value of N is low.

Although most individual deflections are small, their cumulative effects are not. Over long times, uncorrelated deflections from the nearly randomly moving orbits cause each particle's velocity to randomly walk around its original value. Thus the root-mean-square velocity increases from its initial value in proportion to the square root of the number of encounters, or the square root of the time. To estimate this change, we multiply the square of each velocity change from equation (2) by the number of encounters with a given velocity and impact parameter during a unit time and then integrate over the whole range of velocities, impact parameters and times of interest. Finally setting $(\Delta v)^2 = v^2$ gives the stellar dynamical relaxation time for the cumulative small changes to modify the velocity by an amount equal to its initial value. For homogeneous systems near equilibrium with $GM \approx Rv^2$ and a Maxwellian distribution of velocities, this is

$$\tau_R \approx \frac{0.2N}{\ln(N/2)}\tau_c \tag{4}$$

where $\tau_c = R/v \approx (G\bar{\rho})^{-1/2}$ is the dynamical crossing time for a particle with average velocity and $\bar{\rho}$ is the average density.

In globular clusters, galaxies and rich clusters of galaxies $N \gtrsim 10^3$ so $\tau_R \gg \tau_c$. Cumulative small deflections do not amount to much over any one orbital period, but their secular effect can dominate after many orbits. The relaxation time τ_R will vary depending on the geometry, range of masses and velocity and density distributions within a system. For most systems, τ_R exceeds the lifetime of the system, so it cannot have been the primary process for a system's formation and currently relaxed regular roughly spherical appearance.

Systems in which $\tau_R \gg \tau_c$ are essentially 'collisionless' in the sense that their nearly smooth global gravitational force dominates the average orbits of their particles. Other systems in which strong local fluctuations in gravitational forces dominate particle orbits are 'collisional', since these fluctuations produce large-angle scatterings of the orbits. (This standard terminology does not refer to bodily collisions of objects.) Realistic astronomical systems usually combine aspects of both of these idealized categories. For example, local gas clouds, star clumps or dark matter inhomogeneities may scatter stellar orbits from their average smooth paths in GALAXIES.

Even for maintaining a relaxed system near a state of equilibrium, gravitational encounters cannot be the whole story. If they were, the constant average increase in the root-mean-square velocities of all the particles would eventually cause them all to escape, defying the conservation of energy. A second, balancing, process must operate. This is dynamical friction.

Imagine yourself on a particle moving faster than the average speed of the particles around it. In a stationary reference frame attached to your particle, the other particles will appear to stream by. More particles will stream by in the direction you are moving toward than in other directions. The orbits of these excess particles will be deflected slightly by the gravity of your particle. This deflection causes a slight convergence of the orbits behind your particle, opposite the direction of its motion. On average, therefore, there is a statistical excess of particles behind yours. Their excess gravity decelerates the motion of your particle, and tends to reduce it to the average velocity. Conversely, if the speed of your particle is slower than average, there will be a statistical excess of particles passing it in your direction of motion. Their orbits will converge slightly in front of the motion of your particle, and their excess gravitational force will speed up your particle. Thus dynamical friction is a great leveller of velocities. The balance between dynamical friction and two-body acceleration keeps the system close to equilibrium. Therefore τ_R must also be the approximate timescale for relaxation by dynamical friction. Mathematically, a second-order non-linear partial differential–integral equation, known as the Fokker–Planck equation, describes this balance, and it is usually solved numerically.

Dynamical friction also plays another important role in stellar dynamics. If a massive object M (such as a high-mass star in a galaxy, or a large black hole in a galactic nucleus or even a small galaxy in the halo of another larger galaxy) moves rapidly through a field of much less massive objects, m, dynamical friction will cause it to lose kinetic energy, fall deeper into the surrounding gravitational well, speed up while falling, lose more energy and consequently spiral into the center of the larger

system. This helps promote the merging of galaxies, for example (see GALAXIES: INTERACTIONS AND MERGERS). The relaxation time τ_R of equation (4) is decreased significantly by a factor of order m/M. This is because the large mass difference induces *gr*avitational *ex*citati*ons*, known as grexons (also from the Latin 'grex' meaning 'herd' or 'flock'): a collective gravitational excitation in the wake of a massive particle moving through a system of less massive particles. It generally takes the form of a region of statistical overdensity among the less massive particles passing through the wake. These gravitating collective modes of many small masses interact with each other, enhancing their lifetimes and producing a larger effective statistical condensation behind M through which particles of mass m move but linger longer than they would for $M \approx m$. These grexons arise when $M \gg m$ and amplify the gravitational drag.

Other forms of collective excitations can also amplify relaxation in systems which are initially far from equilibrium. This collective relaxation—of which 'violent relaxation' is an extreme case—is much faster than τ_R and closer to the crossing timescale τ_c. Let us start by thinking about a relatively simple case. Suppose one star of mass m initially has zero velocity at the edge of an already relaxed cluster of stars with total mass M and radius R. Details of its orbit would depend on the density distribution of the cluster and the building up of small perturbations, but the star would roughly follow the equation of motion $m\ddot{r} \approx GmMR^{-2}$. Since $\ddot{r} \approx R/t^2$, this would give a characteristic infall timescale $\sim(G\bar{\rho})^{-1/2}$, which is just the crossing time τ_c. We may think of this as the star being scattered by the average force of the entire cluster, i.e. by the 'mean field'. As the star falls inward, the small discrete perturbations of nearby stars will also scatter it, and this 'fluctuating field' will impart some net angular momentum to the star so that it is unlikely to reach the exact center of the cluster. Instead, it will join the other stars in their complicated orbits. The net relaxed orbit of the star comes from the joint effects of the smooth global mean field and the two-body relaxation of the local fluctuating field.

Now let us make the process a little more exciting. Suppose the cluster is not itself relaxed. Then it will not be quasi-static. Parts of it will be falling together, interpenetrating, separating, streaming in different directions and generally flopping around. These represent larger-scale fluctuations—collective modes—which will scatter the incoming star in addition to its scattering by the global mean field and the shorter-scale fluctuations of nearby individual stars. Moreover, the large-scale fluctuations will also be scattering and interacting with each other. With high-amplitude large-mass collective modes fluctuating over a wide range of lengthscales, and on corresponding timescales shorter than τ_c for the entire cluster, individual orbits will relax on timescales closer to τ_c than τ_R. This is collective relaxation, and it may apply to the formation of clusters of stars, galaxies and clusters of galaxies, particularly if they build up by the merging of smaller systems.

Violent relaxation occurs in the extreme limit when collective modes are so chaotic on all scales that each of them lasts for only a short time but is quickly replaced by another such mode elsewhere in the system. None of these modes correlates with one another. Each star moves in a mean field which changes quickly in time as well as in space. Consequently, the energy of each individual star along its orbit is not conserved; only the energy of the entire system remains constant. If this process could continue indefinitely, the velocity distribution of the stars would generally become similar to the Maxwell–Boltzmann distribution for a perfect gas after a timescale τ_c.

However, it does not. On this same gravitational free-fall timescale, τ_c, damping mechanisms destroy the ideal conditions for violent relaxation. In stellar dynamics, as in other systems, damping mechanisms reduce departures from an equilibrium state. Most damping is characterized by dynamical dissipation—the roughly random transfer of relatively ordered (low-entropy) energy into relatively disordered (high-entropy) energy. The transfer may occur among 'particles', as when a stellar cluster or a forming cluster of galaxies ejects a high-energy member so that the remaining cluster becomes more tightly bound. Another example of particle dissipation is the phase mixing of orbits. Generally this involves interactions of stars at slightly different phases of the same, otherwise unperturbed, orbit. As a simple illustration, suppose an isolated spherical cluster of stars, initially completely at rest, starts falling together. The stars will not simply all plunge together into the center. Instead, stars at different distances from the center, i.e. at different phases of their radial orbits, will perturb each other. These perturbations can be large among stars with low relative velocities, and can occur on the dynamical crossing timescale τ_c. Most stars will acquire some angular momentum from these perturbations, although the cluster's net angular momentum remains zero. This further mixes the phase of the orbits, dissipating some of the initially highly ordered radial infall velocities into more random transverse velocities. Eventually, a component of random kinetic energy builds up as a form of heat whose effective pressure resists further collapse of the cluster on the free-fall timescale τ_c. Similar phase mixing of orbits, combined with heat generated by collective relaxation itself, can occur to damp more general collective motions such as those of violent relaxation. More gentle phase mixing can also occur in relaxed galaxies over longer timescales to mix up streaming motions of stars.

Dissipation and damping may also result when particles and waves interact. The waves are moving periodic density perturbations. The best-known case was first found for plasmas by Landau and then applied to stellar dynamics. It occurs even in idealized collisionless systems where particles do not scatter one another significantly. The physical reason for collisionless damping arises from the detailed interaction of a wave with the orbits of background stars which are not part of

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the wave. Thus this process would not show up in a pure continuum approximation. What happens is that some of the background stars will move a bit faster than the wave, others a bit slower, even though their average background number density is constant. The wave exerts a force on these stars and thus exchanges energy with them. On average, the wave gains energy from the fast-moving stars, which therefore amplify the wave, and loses energy to the slow-moving stars, which damp the wave. The net result depends on whether there are more fast or slow stars with velocities near the phase velocity $v = \omega/k$ of the wave. Moreover, the strength of the growth or damping depends on the total net number of fast or slow stars involved. A detailed analysis of this result is complex but, for a roughly Maxwellian velocity distribution of background stars, damping is greatest for waves whose phase velocity ω/k is near the velocity dispersion $\langle v\rangle$ of the background stars. These waves decay on a timescale $\lambda/\langle v\rangle$ during which the stars are able to move through the wave.

Phase mixing, Landau damping and other processes such as trapping by clusters, tidal disruption and small-angle scattering all combine with violent relaxation into a form of collective relaxation which randomizes velocities on a timescale $\sim(G\bar{\rho})^{-1/2}$, provided that the system starts out very far from its eventual quasi-equilibrium state. What is left is a system in quasi-equilibrium with a roughly Maxwellian velocity distribution. No direct collisions are responsible for this end result—unlike the case of a perfect gas—only the non-linear encounters among particles and collective modes.

The virial theorem

This is perhaps the most astronomically important dynamical property of a quasi-equilibrium system. Therefore we describe the virial theorem in some detail. With it, we can estimate the system's total mass from observations of the positions and velocities of its particles. The virial theorem is essentially just a position moment of the self-consistent gravitational equations of motion within the system. To illustrate it in the simplest case, consider a satellite of mass $m^{(\alpha)}$ in a circular orbit around a much more massive object of mass $m^{(\beta)}$. The balance between centrifugal and gravitational forces gives $m^{(\alpha)}v^2/r = Gm^{(\alpha)}m^{(\beta)}/r^2$. Multiplying through by r gives $2K + W = 0$ where $K = m^{(\alpha)}v^2/2$ is the kinetic energy and $W = Gm^{(\alpha)}m^{(\beta)}/r^2$ is the gravitational potential energy. In this circular orbit the instantaneous value and the time average of the energy are identical. For more complicated configurations, we might suspect that this result will still hold for the more general time averages of K and W. It does.

The most general Newtonian equations of motion for a system of gravitating particles are

$$\frac{\mathrm{d}}{\mathrm{d}t}(m^{(\alpha)}v_i^{(\alpha)}) = F_i^{(\alpha)} = m^{(\alpha)}\frac{\partial\varphi}{\partial x_i^{(\alpha)}} = -Gm^{(\alpha)}\sum_{\beta\neq\alpha} m^{(\beta)}\frac{x_i^{(\alpha)} - x_i^{(\beta)}}{|\boldsymbol{x}^{(\alpha)} - \boldsymbol{x}^{(\beta)}|^3} \qquad (5)$$

for the ith components of position and velocity, where the gravitational potential

$$\varphi = G\sum_{\beta\neq\alpha}\frac{m^{(\beta)}}{|\boldsymbol{x}^{(\alpha)} - \boldsymbol{x}^{(\beta)}|} \qquad (6)$$

results from all the other particles. This derivation is general enough to let the particle masses vary with time, by mass loss or accretion, isotropically as we will assume, or even anisotropically with a net 'rocket effect'.

Now multiply equation (5) by $x_j^{(\alpha)}$ and sum over α to take its lowest-order position moment. Since α and β are just dummy indices, we could just as validly multiply through by $x_j^{(\beta)}$. Equivalently, and more elegantly, we could represent the right-hand side as half the sum of both these multiplications, i.e. as

$$W_{ij} = -\frac{G}{2}\sum_\alpha\sum_{\beta\neq\alpha} m^{(\alpha)}m^{(\beta)}\frac{(x_i^{(\alpha)} - x_i^{(\beta)})(x_j^{(\alpha)} - x_j^{(\beta)})}{|\boldsymbol{x}^{(\alpha)} - \boldsymbol{x}^{(\beta)}|^3} \qquad (7)$$

which is symmetric to an interchange of the α and β particles. This is known as the potential energy tensor, W_{ij}.

Rewriting the left-hand side of equation (5) multiplied by $x_j^{(\alpha)}$ gives

$$\begin{aligned}\sum_\alpha x_j^{(\alpha)}\frac{\mathrm{d}}{\mathrm{d}t}(m^{(\alpha)}v_i^{(\alpha)}) &= \frac{\mathrm{d}}{\mathrm{d}t}\sum_\alpha m^{(\alpha)}x_j^{(\alpha)}v_i^{(\alpha)} - \sum_\alpha m^{(\alpha)}v_i^{(\alpha)}v_j^{(\alpha)}\\ &= \frac{\mathrm{d}}{\mathrm{d}t}\sum_\alpha\frac{1}{2}m^{(\alpha)}[(x_j^{(\alpha)}v_i^{(\alpha)} + x_i^{(\alpha)}v_j^{(\alpha)})\\ &\quad + (x_j^{(\alpha)}v_i^{(\alpha)} - x_i^{(\alpha)}v_j^{(\alpha)})] - \sum_\alpha m^{(\alpha)}v_i^{(\alpha)}v_j^{(\alpha)}. \qquad (8)\end{aligned}$$

The terms in parentheses separated by a minus sign are antisymmetric, and since all the other contributions to the moment of equation (5) are symmetric, these antisymmetric terms must be zero. This proves that angular momentum is conserved, since these antisymmetric terms are just the total angular momentum of the isolated system. The symmetric terms in equation (8) may be written as

$$\begin{aligned}&\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\sum_\alpha m^{(\alpha)}(x_j^{(\alpha)}v_i^{(\alpha)} + x_i^{(\alpha)}v_j^{(\alpha)}) - \sum_\alpha m^{(\alpha)}v_i^{(\alpha)}v_j^{(\alpha)}\\ &\quad = \frac{1}{2}\frac{\mathrm{d}^2}{\mathrm{d}t^2}\sum_\alpha m^{(\alpha)}x_i^{(\alpha)}x_j^{(\alpha)}\\ &\quad\quad - \frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\sum_\alpha \dot{m}^{(\alpha)}x_i^{(\alpha)}x_j^{(\alpha)} - \sum_\alpha m^{(\alpha)}v_i^{(\alpha)}v_j^{(\alpha)}. \qquad (9)\end{aligned}$$

Now each of the three summations over α on the right-hand side of equation (9) has a physical interpretation. The first summation is the usual inertia tensor I_{ij}, the second we shall call the mass variation tensor J_{ij} and the third is twice the kinetic energy tensor T_{ij} which incorporates all the motions of all the particles. Combining equations (7) and (9) for the moment of equation (5) then gives the tensor

virial theorem for a system of gravitationally interacting particles:

$$\frac{1}{2}\frac{\mathrm{d}^2 I_{ij}}{\mathrm{d}t^2} - \frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}J_{ij} = 2T_{ij} + W_{ij}. \tag{10}$$

This is an exact result, without any approximations so far. It provides an overall constraint on the system's evolution. Further constraints follow from taking higher-order moments of the equations of motion. Multiplying equation (5) by $x^m v^n$ and summing gives the $(m + n)$th combined spatial and velocity moment. This forms an infinite sequence of virial moments. The more moments are used, the tighter are the constraints on the system's evolution. All the moments taken together usually become equivalent to a complete solution of the original equations of motion (5).

In practice, most astronomical calculations are content with a simplified version of the lowest-order virial equation (5). If the mass loss rate $\dot{m}^{(\alpha)} = 0$, then $J_{ij} = 0$ and the form reduces to that quoted in many texts. For the special rate of mass loss proportional to the mass, $\dot{m}^{(\alpha)} = f(t)m^{(\alpha)}(t)$, the mass loss tensor is proportional to the moment of inertia tensor. A great simplification follows by taking the time average of the virial theorem. For example, the time average of the first term gives

$$\left\langle \frac{\mathrm{d}^2 I}{\mathrm{d}t^2} \right\rangle = \lim_{\tau\to\infty}\frac{1}{\tau}\int_0^\tau \frac{\mathrm{d}\dot{I}}{\mathrm{d}t}\,\mathrm{d}t = \lim_{\tau\to\infty}\frac{1}{\tau}[\dot{I}(\tau) - \dot{I}(0)]. \tag{11}$$

This time average can be zero either if the system is localized in position and velocity space so that $\dot{I}(\tau)$ has an upper bound for all τ or if the orbits are periodic so that $\dot{I}(\tau) = \dot{I}(0)$. Similarly the time average of J_{ij} can be zero if $\dot{m}(t)$ does not increase as fast as t for $t \to \infty$. The terms on the right-hand side of equation (10) remain non-zero over any time average, so

$$2\langle T_{ij}\rangle + \langle W_{ij}\rangle = 0. \tag{12}$$

The usual (contracted) form of the virial theorem is obtained by setting $i = j$ and summing over $i = 1, 2, 3$ to give

$$2\langle T\rangle + \langle W\rangle = 0 \tag{13}$$

where T and W are the entire kinetic and potential energies of the system.

The virial theorem describes reasonably bound, quasi-stable clusters of stars and galaxies. Its usual application is to estimate the mass of these clusters by writing equation (13) in the approximate form

$$V^2 = \gamma\frac{GM}{R}. \tag{14}$$

This is similar to the form for a circular satellite orbit discussed earlier, but now V^2 is the velocity dispersion of objects in the cluster, R is the cluster's radius and M is its total mass. The constant γ is usually of order unity and depends on the precise operational definitions of V, R and M, especially if the particle masses are not identical. Other factors which influence γ when trying to deduce M are projection effects in transverse positions, loss of one position and two velocity components, departures of time averages from the instantaneous snapshots of observations, questions of cluster membership and selection of a limited number of particles for observation. Each of these effects depends on the particular circumstances of an individual cluster. Their combination introduces considerable uncertainty into γ, but this can often be estimated with computer simulations.

Virial estimates of the masses of CLUSTERS OF GALAXIES have been made since the 1930s. A succession of more accurate results with more complete samples and better simulations, which continues to the present, revealed clear discrepancies between the virial mass of many clusters and their mass estimated from the luminosities of their individual galaxies. Unless cluster formation proceeded by a radically different route from the condensation processes discussed currently, this discrepancy suggests that the amount of 'DARK MATTER' in clusters is about five times the amount of luminous matter in galaxies. This gives roughly one-fourth of the total mass needed for a closed Einstein–Friedmann universe. The form of this dark matter and its total amount are two of the main problems of modern astronomy.

Distribution functions

Rather than dealing with the positions and motions of each identifiable particle individually, stellar dynamics often finds a less detailed description based on distribution functions to be more useful and solvable. These distributions represent the probability that any arbitrary particle in the system has a particular property of interest. Usually stellar dynamics is concerned with the single-particle distribution $f(\boldsymbol{r}, \boldsymbol{v})$ for the number of particles having position $\boldsymbol{r}$ and velocity $\boldsymbol{v}$. Integrated over all velocities, this gives the density as a function of position. Integrated over all positions, this gives the velocity distribution. Integrated over both position and velocity, it gives the total number of particles in the system. When $f(\boldsymbol{r}, \boldsymbol{v})$ is normalized to this total number, it becomes a probability distribution. Then $f(\boldsymbol{r}, \boldsymbol{v})\,\mathrm{d}\boldsymbol{r}\,\mathrm{d}\boldsymbol{v}$ is the probability that a particle is in the differential volume $\mathrm{d}\boldsymbol{r}$ around $\boldsymbol{r}$ and has a velocity in the range $\mathrm{d}\boldsymbol{v}$ around $\boldsymbol{v}$.

Other types of distribution functions are also useful. For example, the two- particle distribution $f(\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{v}_1, \boldsymbol{v}_2)$ describes the probability that of any two particles one is in the volume $\mathrm{d}\boldsymbol{r}_1$ with velocity in the range $\mathrm{d}\boldsymbol{v}_1$ and the other is simultaneously in $\mathrm{d}\boldsymbol{r}_2$ with velocity in $\mathrm{d}\boldsymbol{v}_2$. This two-particle distribution may be written as the product of two single-particle distributions plus terms representing any correlations that may be present between particles in the two volumes or the two velocity ranges. Similarly, a hierarchy of three-, four-, etc particle distributions and correlations may be built up. Eventually it will reach the N-particle distribution which gives a complete description of the positions and velocities of all N particles in the system. This would then be equivalent to specifying the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

position and velocity of every particle—the most detailed description possible. A related form of distribution function, $f(N)$, concentrates on cells rather than particles and specifies the probability that a cell of given size and shape contains N particles.

All these distribution functions may generally have anisotropic dependences on position and velocity and will evolve with time unless they are in a stationary equilibrium state. Anisotropic distribution functions and their properties have been widely explored in recent years. Their complexity provides useful descriptions of stellar motions in both spiral and elliptical galaxies.

The simplest evolution for the one-particle distribution function $f(\boldsymbol{r}, \boldsymbol{v}, t)$ occurs in collisionless systems and follows the collisionless Boltzmann equation. Here collisionless means that particle orbits proceed smoothly under the influence of just the mean field. There are no scatterings by other particles or by local fluctuations. Under these conditions $f(\boldsymbol{r}, \boldsymbol{v}, t)$ satisfies an equation of continuity. This is equivalent to its total time derivative, following the motion through a 6-dimensional position–velocity phase space, being zero:

$$\frac{\mathrm{D}f}{\mathrm{D}t} = \frac{\partial f}{\partial t} + \boldsymbol{v} \cdot \boldsymbol{\nabla} f + \dot{\boldsymbol{v}} \cdot \boldsymbol{\nabla}_v f = 0. \qquad (15)$$

Equation (15) is the collisionless Boltzmann equation—one of the most useful descriptions of stellar dynamics. Notice that the gradients in position and in velocity space are treated equivalently. Although, written this way, it looks like a fairly simple linear partial differential equation for $f(\boldsymbol{r}, \boldsymbol{v}, t)$, it is really a complicated non-linear differentio-integral equation. This is because the gravitation force, proportional to the acceleration $\dot{\boldsymbol{v}} = \boldsymbol{\nabla}\phi$, is a function of the density which is itself an integral of $f(\boldsymbol{r}, \boldsymbol{v}, t)$ over velocity space. This relation is obtained from Poisson's equation, $\nabla^2\phi(\boldsymbol{r}, t) = -4\pi G\rho(\boldsymbol{r}, t)$, and together with the relevant initial and boundary conditions leads to self-consistent solutions.

Very few solutions are known in closed analytic form; most are results of numerical integrations or perturbation theory. The best-known solution occurs for an idealized homogeneous, isotropic, uncorrelated equilibrium distribution. It is the Maxwell–Boltzmann distribution with a Gaussian distribution of velocities. Solutions of equation (15) also provide a zero-order approximation for systems of particles such as globular clusters and rich clusters of galaxies. Their corresponding spatial density is spherically symmetric, decreasing with radius. Such isothermal spheres have to be truncated to describe clusters of finite mass. Truncation by tidal cutoffs, evaporation, inflow, etc for realistic systems will modify their distribution functions.

Spatial and velocity moments of the collisionless Boltzmann equation, similar to those leading to the virial theorem and its generalizations described earlier, yield the Jeans equations of 'stellar hydrodynamics'. These are analogous to the usual fluid equations of hydrodynamics. However, because short-range atomic interactions dominate fluids, it is a much better approximation to truncate the moment equations at low order for fluids than it is in the stellar dynamical case. Moreover, the general stellar hydrodynamical equations are anisotropic in their spatial and velocity coordinates.

Generalizations of the collisionless Boltzmann equation have been developed to incorporate local fluctuations, such as those described earlier, which lead to dynamical relaxation, evaporation and other instabilities. The most useful of these is the Fokker–Planck description which represents the total gravitational field as the sum of two parts: the smooth average long-range field and the local fluctuating field due to near-neighbor particles. These fluctuations cause the particles to diffuse in velocity space as well as in configuration space. They also incorporate the dynamical friction effects, mentioned earlier, which prevent excessive velocities from being reached. The Fokker–Planck equation provides a more accurate account of processes such as evaporation, core collapse and oscillations which can occur in globular clusters.

The most general and rigorous description of stellar dynamics, and therefore the least solvable, is known as the BBGKY hierarchy (after the initials of its early developers in other subjects, Born, Bogoliubov, Green, Kirkwood and Yvon). It starts from Liouville's equation which is an equation of continuity similar to equation (15) but in a $6N$-dimensional (Gibbs) phase space rather than in the 6-dimensional (Boltzmann) phase space. Here N is the number of physical particles in the system and each point in the Gibbs phase space of $3N$ position plus $3N$ velocity dimensions represents the state of the entire system of $6N$ particles at a given time. As the system evolves, its representative point moves continuously and smoothly through this phase space because there are no external forces outside the system to perturb it. Thus the Liouville continuity equation is exact. It is a first-order linear differential equation. The problem is that it has $6N$ variables, plus time. In fact, it is just a condensed way of representing the orbits of all the particles in the system.

To make this description useful, it is necessary to successively integrate out all but $6(N-1), 6(N-2), \ldots, 6$ of the $6N$ variables in the full distribution function. This leaves a set of N coupled non-linear integro-differential equations for all the N, $N-1$, $N-2, \ldots$, one-particle distribution functions—the BBGKY hierarchy. The entire set is equivalent to the equations of motion for all N particles. Truncating the lowest-order equation for $f(\boldsymbol{r}, \boldsymbol{v}, t)$ by neglecting its coupling to $f(\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{v}_1, \boldsymbol{v}_2, t)$ is equivalent to the collisionless Boltzmann equation. Retaining this coupling, but neglecting any higher-order coupling, gives essentially the Fokker–Planck equation. This formalism has been much studied and gives great insight into the physical nature and relations among different stellar dynamical descriptions. It has found important applications in understanding the linear growth of two- and three-particle correlation functions in galaxy clustering, as well as for plasma physics and the theory of imperfect fluids.

Thermodynamic descriptions

Particle and distribution function descriptions are mathematically complex because they contain much detailed microscopic information about a stellar dynamical system. Thermodynamic descriptions are mathematically much simpler because they deal mainly with macroscopic information which averages over the microscopic detail. This relative simplicity has provided considerable physical insight into the behavior of stellar dynamical systems.

Since the macroscopic properties generally change with time (e.g. even in virialized clusters, particles slowly evaporate), stellar dynamical systems cannot be in equilibrium. Therefore it might be thought that thermodynamics, which is primarily an equilibrium theory, could not apply. Often, however, the timescales for departures from equilibrium are very long, and singular states are essentially unattainable over shorter times. As a result, thermodynamics provides a good approximation for the periods of interest. The system may be in quasi-equilibrium, during which it evolves through a sequence of equilibrium states. In simple systems, each state can be described well in terms of average macroscopic thermodynamic variables such as temperature, pressure, chemical potential, internal energy, volume, total number of particles and entropy, but these quantities change on a timescale which is slow compared with the timescale for a local microscopic configuration of particle positions and velocities to change.

Symmetry properties of different physical systems strongly influence their thermodynamic descriptions. For example, infinite statistically homogeneous systems—which may represent galaxy clustering—have rotational and translational symmetry everywhere. However, finite spherical systems have rotational symmetry only at their center and translational symmetry nowhere. Consequently these infinite systems are described by a grand canonical ensemble in which energy and particles can move across boundaries. Finite, isolated clusters, on the other hand, are described either by a microcanonical ensemble with no transport across boundaries or by a canonical ensemble with only energy transport. (An ensemble is a collection of systems with the same average macroscopic properties but different microscopic configurations consistent with the macroscopic averages.) This leads to differences in their distribution functions and fluctuation spectra.

Thermodynamic behavior in systems dominated by gravity is often 'counterintuitive', although really just in the sense that they behave differently from more familiar systems of particles without long-range, unshielded, attractive forces. For example, if one removes energy from a self-gravitating cluster of stars, it becomes hotter. Adding energy makes it cooler. Thus it has a negative specific heat. In fact, this follows simply from the virial theorem for a bound system. Slowly adding energy makes the system's gravitational well less negative. To maintain their changing quasi- equilibrium state, the particle velocities must decrease on average, and the system grows cooler. It is essentially the same effect as adding energy to a satellite orbit around a massive body, and so it should be, since the virial theorem applies to both cases.

Applied to finite, isolated spherical clusters of stars, gravitational thermodynamics has been especially useful in elucidating their global instabilities. The isothermal sphere, where all particles have the same mass and temperature, provides a relatively simple illustration. Its density is obtained by solving the collisionless Boltzmann equation and Poisson's equation for these conditions, or, more easily but less accurately, by solving the gravitational hydrostatic equations with an isothermal gas equation of state. It has a central core, and density $\rho \propto r^{-2}$ in the outer parts, and is usually truncated to keep its mass finite. (Other stellar clusters with more general equations of state similar to polytropic stars can also be manufactured to provide simple models.)

The stability of such an isothermal sphere depends on the relation between its total energy and its total entropy. Systems of the same total energy may have different entropies depending on their size and internal distribution. If the entropy has a local maximum for a given energy, then that configuration is stable to small fluctuations (but possibly metastable to large changes). If the entropy does not have a local maximum, then the system of a given energy can redistribute itself internally to increase its entropy, and the situation is unstable. Such analysis, originally done by Antonov, for an isothermal sphere confined to a spherical box shows that, if the ratio of the central to the boundary density exceeds 709, the system becomes unstable. It tends to evolve away from the isothermal sphere density distribution into a denser central core surrounded by a much less dense halo. Similar core–halo evolution is also found in numerical simulations. Its underlying dynamical mechanism is the slow evaporation of stars which have accumulated just enough energy to escape by their interactions with the fluctuating gravitational field of neighboring stars. Since the total gravitational energy of the isolated sysem is conserved, its core becomes denser with its energy more negative in order to compensate the positive total energy of the escaping stars.

An infinite statistically homogeneous system provides a contrasting application of gravitational thermodynamics. The cosmological many-body problem is an example. In its simplest case, we start with a uniform random (Poisson) distribution of identical point masses throughout the universe and ask how this distribution changes as the universe expands. In the usual Einstein–Friedmann cosmological models, the cosmological expansion exactly compensates the smooth long-range component of the gravitational field. This leaves only the relatively local fluctuations caused by the discreteness of the particle gravitational fields and by any clustering. These fluctuations can be described by an equation of state which incorporates the gravitational interaction into thermodynamic quantities such as the internal energy and pressure.

Because the universe generally expands more slowly than the timescale for particle configurations within local fluctuations to change, it undergoes a quasi-equilibrium evolution. At any time an equilibrium thermodynamic state provides a good description of the clustering. Its thermodynamic quantities change slowly as the universe expands adiabatically.

Infinite statistically homogeneous systems have a uniform density when averaged over sufficiently large scales or over an ensemble of smaller scales. These infinite systems are characterized by the fluctuations over various scales of macroscopic quantities around their averages. The fluctuations most closely related to observations are the particle distribution functions $f(N, V)$ which give the probability for finding N particles (e.g. galaxies) in a randomly placed volume of size V. Applying thermodynamic fluctuation theory to the cosmological many-body equation of state gives a relatively simple formula for this distribution:

$$f(N, V) = \frac{\bar{N}(1-b)}{N!}[\bar{N}(1-b) + Nb]^{N-1}\, \mathrm{e}^{-\bar{N}(1-b)-Nb}. \quad (16)$$

Here $\bar{N} = \bar{n}V$ is the average number in the volume V for the average number density $\bar{n}$. The quantity $b = -W/2K$ is the ratio of the gravitational correlation energy to twice the kinetic energy of random motions, averaged over all volumes of size V having a particular shape. The correlation energy, W, is the integral of the r^{-1} interparticle gravitational potential multiplied by the two-particle correlation function $\xi(r)$ over the volume. $\xi(r)$ is the average excess over the random Poisson probability for finding a particle in a differential volume element at a distance r from another particle.

In a completely uncorrelated initial Poisson distribution, $\xi(r) = 0$, $W = 0$ and consequently $b = 0$. In this limit, the distribution function of equation (16) does indeed reduce to the standard Poisson form. As the system evolves, regions where near-neighbor points happen to be closer than average cluster as a result of their enhanced gravity. These clusters subsequently cluster themselves and a hierarchy of non-linear clustering, with a wide range of amplitudes and scales, represented by the increasing value of b, gradually builds up. In the Einstein–Friedmann universe, this non-linear evolution of b can be calculated analytically and it asymptotically approaches unity as the universe expands. This asymptotic limit represents bound clustering on all scales, and is strictly reached only for $\Omega_0 = 1$.

A velocity distribution function can also be derived from equation (16). Compared with the Maxwell–Boltzmann distribution for finite isothermal spheres, the velocity distribution function for the cosmological case is much broader. This is because it includes all levels of clustering, from isolated field galaxies to the richest bound clusters. Numerical computer simulations of the cosmological many-body system verify equation (16) as well as its associated velocity distribution function. Observations of galaxies on the sky and in three dimensions, using COUNTS IN CELLS as well as VOID and near-neighbor statistics, are also in very good agreement with equation (16). The currently observed value of b is about 0.75.

The BBGKY kinetic hierarchy, mentioned earlier, has also been used to examine hierarchial galaxy clustering. It is partially solvable for the two- and three-particle correlation functions in the linear regime. However, it generally contains less usable observational information than the distribution functions. There are also many more complicated models of galaxy clustering, involving hot and cold dark matter, various forms of initial density and velocity perturbations, biases between the galaxies and dark matter, etc, but their detailed applicability to our universe remains unclear.

Many applications of these main physical descriptions of stellar dynamics—particle orbits, kinetic theory, distribution functions and thermodynamics—have developed over the last century. They have helped provide an understanding of the formation, relaxation and dynamical evolution of star clusters within galaxies. They help explain the streaming motions and arms of spiral galaxies, as well as the triaxial shapes of elliptical galaxies. Combined with the possible existence and effects of massive black holes in galactic nuclei, stellar dynamics helps describe the evolution of the nuclei and the feeding of their black holes. On a larger scale, stellar dynamics gives a background for understanding the formation, relaxation and evolution of galaxy clusters, incorporating effects of their internal dark matter. Even more generally, the principles of stellar dynamics play an important role in accounting for the structure of matter over the largest scales in the universe.

Although stellar dynamics is an old and well-established subject, it is often rejuvenated by new insights and new applications. Some interesting areas for future further developments include the detailed links between dynamics and thermodynamics, implications for galaxy clustering, galaxy and cluster merging, distributions around black holes in galactic nuclei, counterstreaming in galaxies and the development of stellar motions in large star-forming regions.

Stellar Evolution

Stars evolve because they lose energy through radiation from their hot surfaces. As a result, there is a general tendency for the star to contract under gravity. This is partly stopped by the release of energy from nuclear reactions. However, once the nuclear fuel is exhausted, gravity gets the upper hand and the star ends its life as a compact object: a white dwarf, a neutron star or a black hole, the last representing the ultimate victory of gravity.

In the nuclear reactions lighter elements are fused into heavier; it is generally believed that all elements but the very lightest have been formed in this way. Because of mass loss the elements so formed can later be incorporated in new generations of stars and their planetary systems. Thus we are all made of star-dust.

An overview of stellar evolution

The energy radiated from the star must be supplied from changes in the stellar interior. A star essentially has three sources of energy: the release of gravitational energy through contraction which makes the star more tightly bound; cooling through emission of the internal thermal energy; the generation of energy through nuclear fusion whereby the ligher nuclei fuse into heavier, more tightly bound nuclei. During most of the life of a star, the nuclear processes dominate the energy production; this requires that the temperature is sufficiently high that the nuclei can overcome their mutual Coulomb repulsion. Fusion leads to the build-up of successively heavier elements in the core of the star (see NUCLEAR REACTION RATES). These changes in the composition of the deep interior cause dramatic changes in the star's structure and surface properties such as luminosity and surface temperature, reflected in the observable characteristics of the star.

The general principles of stellar evolution may be described on this background. Stars form from condensations in interstellar clouds. During the initial contraction the energy output comes from the gravitational energy released as a result of the contraction. At the same time, this leads to heating of the stellar interior. When the temperature becomes sufficiently high, nuclear reactions set in. Generally speaking, the first reactions are those between nuclei of the smallest charges, and hence with the lowest Coulomb barrier. Thus the initial reaction is the fusion of hydrogen into helium. Once the nuclear energy generation balances the energy loss from the stellar surface, the contraction essentially stops. Evolution then takes place on a nuclear time scale, as a result of the gradual change in the structure of the star as hydrogen is converted into helium. In the solar case, this phase of central hydrogen 'burning' lasts around 10 Gyr.

When hydrogen has been consumed at the center, the star is left with a core consisting of helium and the original heavier elements; outside this core the temperature is typically sufficiently high for hydrogen fusion to continue, in what is called a *shell source*. This adds helium to the core, causing it to contract; the resulting release of gravitational energy partly leads to heating of the core, until the temperature becomes sufficiently high that the next nuclear reactions, the fusion of three helium nuclei into a carbon nucleus, can take place. At the same time the star may still have a hydrogen-fusion shell source. This sets the general pattern of the nuclear evolution of the star: fusion reactions in the core, alternating with core contraction and heating until the next stage of nuclear reactions can take place, and with possible shell sources outside the core with fusion of lighter elements.

The evolution of stars is conveniently illustrated in *the theoretical Hertzsprung–Russell diagram* (see also HERTZSPRUNG–RUSSELL DIAGRAM), where the stellar luminosity is plotted against surface temperature (more precisely the *effective temperature*; see below) as shown in figure 1. Following observational convention, the temperature increases towards the left. The ZAMS marks the stars that have just started core hydrogen burning. Also marked is the termination of the main sequence where core hydrogen burning has finished. The evolutionary sequences shown end on *the red-giant branch* where the stellar radii grow dramatically; later evolutionary stages will be illustrated below.

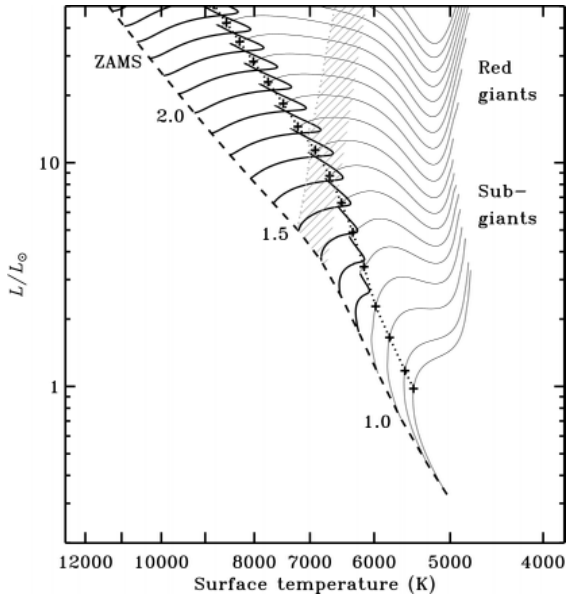

Figure 1. Evolutionary tracks of stars in terms of surface temperature and total luminosity ($L_\odot$ is the solar luminosity) are shown by the solid curves (a few are labeled by the stellar mass, in units of the mass $M_\odot$ of the Sun). The *zero-age main sequence* (ZAMS; dashed) marks stars just starting fusion of hydrogen into helium, while the dotted curve shows the end of core hydrogen burning. Bolder curves show parts of the tracks where the star has a convective core. Stars with surface temperatures below 7000 K, indicated by the hatching, have convective envelopes.

An important consequence of stellar evolution is the fusion of lighter elements into heavier, starting from the lightest, hydrogen. These processes take place in the deep interiors of the star; however, during late stages of evolution the products of the reactions may be spread through mixing by convective motions throughout the star, hence becoming visible in its observable surface composition. Also, mass loss from the star, either gradual or explosive, may distribute the elements generated in the stellar interior in the interstellar matter where it can be incorporated into newly formed stars and planets. Indeed, there is strong evidence that essentially all elements heavier than helium have been formed in this manner, from the mixture of hydrogen and helium resulting from the big bang (see COSMOLOGY: STANDARD MODEL and NUCLEOSYNTHESIS). Thus to understand the origin of the chemical elements and, finally, our own origins, we need to understand the structure and evolution of stars.

Modelling stellar evolution

Most of our understanding of stellar evolution is based on rather simplified numerical models (see also STELLAR INTERIORS); interestingly, despite their simplifications, the models are generally in good overall agreement with the available observational data. The models are mostly taken to be spherically symmetric (thus neglecting effects of rotation) and most often neglect possible mass loss or accretion. Also, many potential hydrodynamical instabilities, which might cause mixing of regions of otherwise inhomogeneous composition and hence affect the evolution, are ignored. In contrast, the detailed properties of stellar matter such as equation of state, radiative transport and energy generation, often referred to as the microphysics, are treated in considerable detail. This defines what might be called the 'standard' theory of stellar evolution and will be the basis for most of the discussion here. These simplified models are in fact able to reproduce quite successfully many aspects of the observed properties of stars. In particular, the models are in reasonable agreement with the detailed helioseismic inferences of solar internal structure (see SOLAR INTERIOR: STANDARD MODELS), although there remain highly significant discrepancies indicating remaining, and so far not definitely identified, deficiencies in the calculations. In the case of other stars, the comparison between observations and models is generally based just on the overall surface properties of the stars, which may well hide problems of potentially serious consequences in the modelling of late stages of stellar evolution.

Further complications arise in the, not uncommon, case where stars are members of close binary-star systems. Here there are dramatic episodes of mass transfer, when one star expands as a result of its evolution, completely changing the subsequent evolution of the system. The result is a bewildering richness of evolutionary scenarios, which is only beginning to be explored; many types of such interacting binary stars have been identified observationally, including also possible end products of the evolution, such as binary pulsars (e.g. Hulse–Taylor pulsar). This is discussed briefly at the end of the article.

Basic properties of stars

The properties of stellar interiors are treated in some detail in STELLAR INTERIORS and SOLAR INTERIOR: STANDARD MODELS as well as in several articles on the physical properties of stars. Here some simple aspects are considered which will be useful in the following.

The ways in which energy is transported in a star, from the central region where energy generation takes place to the surface, play an important role in its structure and evolution. Very generally, energy transport determines the temperature gradient in the star; as in any physical system, heat flows towards lower temperature, at a rate determined by the effective thermal conductivity and the decrease in temperature. The precise relation depends on the mechanism of heat transport. In large parts of most stars, energy is transported by radiation; here the rate of energy transport is characterized by the opacity κ, defined such that the mean free path of a photon is $1/\kappa\rho$, ρ being the density (see SOLAR INTERIOR: EQUATION OF STATE AND OPACITY). However, in some parts of the star the temperature gradient required for radiative transport becomes so steep that an unstable situation arises: matter displaced outwards, adiabatically, finds itself lighter than the surroundings and hence continues to rise. In this way *convective motion* is set up, whereby rising hot elements of fluid and cold sinking elements dominate the energy transport (for a more precise definition of the instability condition, and a description of how convection may be treated, see STELLAR INTERIORS and SOLAR INTERIOR: CONVECTION THEORY).

The distribution of convective regions plays a major role in the evolution of stars. This is illustrated for ZAMS stars in figure 2. In low-mass stars the comparatively low temperature in the outer layers results in a high opacity and hence in a convective envelope, whose depth increases rapidly with decreasing mass of the star; at $M \lesssim 0.25 M_\odot$ the stars become fully convective. In a $1 M_\odot$ ZAMS star the convective envelope contains only about 3% of the mass, although it extends over almost 30% of the radius. Stars only slightly more massive than the Sun develop convective cores, the extent of which increases with increasing mass. This is caused by an increasing concentration towards the center of energy generation, reflected in figure 2 by the curves marking where 50% and 90% of the luminosity is generated. The change in the distribution of energy generation, in turn, arises because of a change in the dominant processes by which hydrogen is fused to helium (see also SOLAR INTERIOR:

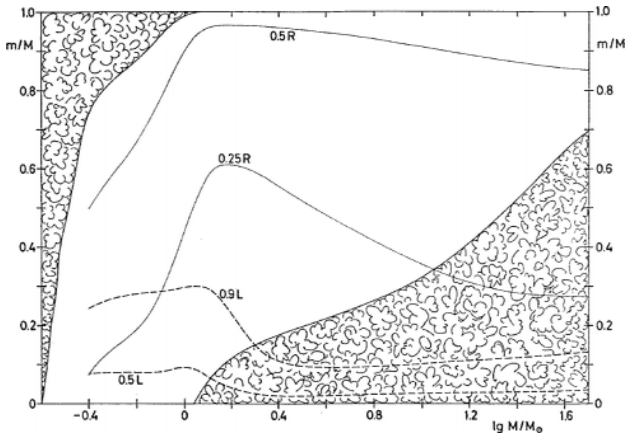

Figure 2. Structure of ZAMS stars. The horizontal axis shows the logarithm of the mass of the star (in solar units), whereas the vertical axis indicates position in the star, in terms of the mass m interior to a given point. 'Cloudy' areas indicate the presence of convection. The two solid curves show the positions where the distance r to the center is 0.25 and 0.5 times the surface radius. The dashed curves show the positions interior to which 50% and 90% of the stellar luminosity is generated.

ENERGY GENERATION). At lower mass, for $M \lesssim 1M_\odot$, the reactions are dominated by the pp chains, controlled by the fusion of two hydrogen nuclei, with a moderate temperature sensitivity. In contrast, at higher mass the dominant reaction is the CNO cycle, where the controlling reaction is the fusion of hydrogen and ^{14}N; the higher Coulomb barrier makes this reaction far more temperature sensitive than the pp chains, leading to the stronger concentration of the reactions towards the center.

Realistic studies of stellar structure and evolution requite detailed numerical calculations. However, several aspects can be understood, at least in a qualitative sense, from simple scaling relations. (These can be given a more precise meaning under rather restrictive assumptions on the physics of the stellar interior.) From the condition of hydrostatic equilibrium it may be shown that the internal pressure P scales as

$$P \sim \frac{GM^2}{R^4}$$

where G is the gravitational constant and M is the mass of the star. Assuming also that the stellar matter approximately satisfies the ideal gas law, the internal temperature may be estimated as

$$T \simeq \frac{GM\mu}{\mathcal{R}R} \tag{1}$$

where μ is the mean atomic weight of the constituents of the gas and $\mathcal{R}$ is the gas constant.

It is important to realize the meaning of these relations. They do not provide accurate estimates of conditions in stellar interiors (although, for example, the relation for T does reproduce the central temperature of detailed stellar models reasonably well). However, they *do* indicate how these conditions depend on the overall properties of the stars, i.e. their masses, radii and chemical composition. For example, equation (1) shows that as the star grows older, converting hydrogen into helium and thereby increasing μ, there is a general tendency for the temperature to increase.

If energy transport occurs predominantly by radiation, equation (1) can be used to estimate the luminosity of the star. The result depends on the detailed dependence of opacity on temperature and density. In relatively low-mass stars where the temperature is generally rather low, the opacity is approximately given by *Kramers' approximation*, $\kappa \propto Z(1 + X)\rho T^{-3.5}$, where X and Z are the abundances by mass of hydrogen and elements heavier than helium, respectively. In higher-mass, and hence hotter, stars, on the other hand, the opacity is dominated by scattering on free electrons, $\kappa \simeq 0.02(1 + X)$ m^2 kg^{-1}. Accordingly, we obtain as estimates of the luminosity

$$L \propto (1+X)^{-1}Z^{-1}M^{5.5}R^{-0.5}\mu^{7.5} \qquad \text{low-mass stars} \tag{2}$$

$$L \propto (1+X)^{-1}M^{3}\mu^{4} \qquad \text{high-mass stars.} \tag{3}$$

From an observational point of view, it is convenient to characterize the star by its surface luminosity and temperature. More precisely, one introduces the *effective temperature* $T_{\rm eff}$ of the star, as the surface temperature of the star at the given radius and luminosity, had it been radiating as a black body (cf EFFECTIVE TEMPERATURE SCALE AND BOLOMETRIC CORRECTIONS). Thus the radius R, luminosity L and effective temperature $T_{\rm eff}$ are related by

$$L = 4\pi\sigma R^2 T_{\rm eff}^4 \tag{4}$$

where σ is the Stefan–Boltzman constant. Hence equation (2) may also be written as

$$L \propto (1+X)^{-0.8}Z^{-0.8}M^{4.4}T_{\rm eff}^{0.8}\mu^{6} \qquad \text{low-mass stars.} \tag{5}$$

This reflects, for example, roughly speaking the relation between the change in luminosity and effective temperature as the star evolves towards the red-giant branch. For higher-mass stars, evidently, the corresponding relation is given directly by equation (3).

These expressions for the luminosity are based on the assumption that the stars are dominated by radiative energy transport. As the stars approach the red-giant branch they develop deep outer convective envelopes and

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

hence this assumption no longer holds. For predominantly convective stars, the structure is to a large extent controlled by the surface conditions. As a result, the stars occupy the *Hayashi track*, at an effective temperature which depends little on the luminosity or mass of the star. This corresponds to the nearly vertical red-giant branch in figure 1; the Hayashi track joins the main sequence at low stellar mass where, as noted above, the stars become fully convective. Also, it may be shown that the region on the cool side of the Hayashi track is 'forbidden': it is not possible to construct stable stellar models in hydrostatic equilibrium in this region.

Stellar energy sources

Gravitational contraction reduces (makes more negative) the gravitational potential energy of the star. It follows from *the virial theorem* that of the energy so liberated approximately half goes into increasing the thermal energy of the gas whereas the other half is lost from the star, in the form of radiation from the surface. In general, the increase in the thermal energy leads to an increase in the temperature of the stellar interior. It is this increase in temperature which allows the nuclear fusion reactions to take place.

Fusion of two nuclei requires that they overcome their mutual Coulomb repulsion. For this to be possible, their thermal energy has to be sufficiently high, requiring a temperature of at least several million K. Even so, the energy of the nuclei is far below the Coulomb energy of repulsion when the two nuclei are brought so close together that they touch. Thus, according to classical mechanics no reaction is possible. What enables the reactions to take place is the quantum-mechanical phenomenon of *tunnelling*, leading to a finite probability for the two nuclei to interact even if according to classical mechanics they are kept apart. However, in most stars this is an exceedingly slow process: the average lifetime of a given hydrogen nucleus at the center of the Sun is of order 5 Gyr (billion years). Consequently, the rate of energy release per unit mass is modest: the average rate of energy generation in the solar core is only around 0.001 W kg^{-1}, about 3 orders of magnitude below that of an average human. On the other hand, because of the large mass of the Sun, the total energy generation is enormous, around 4×10^{26} W.

However, fusion can only provide energy as long as the nuclei become more tightly bound when they fuse. The nuclear binding energy has a maximum among the iron-group elements; thus the nuclear energy generation stops when matter has been converted into these elements. At this point gravitational contraction is the only remaining effective energy source: the central parts of the star undergo catastrophic collapse, releasing vast amounts of gravitational potential energy and causing the star to explode as a supernova (see SUPERNOVAE). This stage, however, is only reached for massive stars; in stars of mass below around 10 times the mass of the Sun, the core temperature never becomes so high that the final nuclear reactions take place. Such stars undergo substantial mass loss, leaving behind the compact core of the star, in the form of WHITE DWARFS, which subsequently cool through radiation of its internal thermal energy. This is the likely final fate of the Sun, for example.

It is instructive to consider the amount of energy available to the star from gravitational contraction and nuclear reactions. The typical energy, per unit mass, available from gravitational contraction is determined by the gravitational potential of the star, whose magnitude may be estimated as GM/R, where G is the gravitational constant, and M and R are the mass and surface radius of the star. Using the solar mass, $M_\odot = 1.989 \times 10^{30}$ kg and the solar radius $R_\odot = 6.96 \times 10^8$ m, the result is 2×10^{11} J kg^{-1}. The energy available from fusion may be obtained, according to the relativistic equivalence between mass and energy, from the difference in mass between the nuclei taking part in, and the nucleus resulting from, the reaction. In fusion of hydrogen to helium, the energy lost is approximately 0.7%. Thus the available energy from this reaction, per unit mass, is $0.007c^2 = 6 \times 10^{14}$ J kg^{-1}, where c is the speed of light. The maximal energy available from fusion results from the, hypothetical, reaction where hydrogen fuses to iron-group elements, the most tightly bound nuclei; the resulting relative mass difference is 0.9%, corresponding to 8×10^{14} J kg^{-1}. (It should be noticed that the first of the series of fusion reactions, from hydrogen to helium, produces 75% of the total amount of energy available.)

From these energy estimates we can obtain rough estimates of the characteristic time scales of different phases of stellar evolution. The total energy available to a $1M_\odot$ star from gravitational contraction is, assuming again solar radius, approximately 4×10^{41} J; at the solar luminosity of around 4×10^{26} W, this would last for about 10^{15} s, or around 30 Myr (million years). This, therefore, is the characteristic lifetime for a star whose energy comes from gravitational contraction; it is generally known as the *Kelvin–Helmholtz time scale*. (From the fact that it is much shorter than the age of the solar system, around 5 Gyr, it immediately follows that other sources of energy are required for the Sun.) To estimate the total energy available from nuclear reactions, we must take into account that only in around 10% of the mass of a star is the temperature sufficiently high for the reactions to be efficient; thus the total energy produced from hydrogen fusion, in a $1M_\odot$ star, is around 1.2×10^{44} J. At solar luminosity this corresponds to a lifetime of 3×10^{17} s, or 10 Gyr. Thus the Sun is approximately half-way through the phase of central hydrogen fusion. It should also be noticed that since the luminosity of stars generally increases with age, and

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

given the smaller energy release in later fusion reactions, the phase of hydrogen fusion occupies the dominant part of a star's active life; thus we may expect that most of the stars observed are in this phase.

It should finally be noted that collapse to a much smaller radius may release very large amounts of energy. This is the case during a supernova explosion, where the central parts of the star collapse to nuclear densities, resulting in a core with a mass of order $1M_\odot$ and a radius of around 10 km. Here the gravitational potential is of order 10^{16} J kg^{-1}, i.e. around 10% of the rest-mass energy. The total energy released in this collapse, of order 2×10^{46} J, is what powers the supernova explosion.

Early life of a star

The birth of a star takes place in a dense interstellar cloud (a so-called *molecular cloud*), when a part of the cloud becomes unstable to gravitational collapse and begins to contract. The initial phases of the cloud collapse occur on dynamical time scales and undoubtedly involve effects of turbulence, magnetic fields, rotation, mass loss and accretion, none of which is understood in detail. These processes give rise to spectacular observational effects such as extended jets, and the formation of disks around young stellar objects which may later develop into planetary systems. For further details on these processes, see STAR FORMATION.

In the early phases the evolution is dominated by the interaction between the protostar and the surrounding material which continues to be accreted (see PRE-MAIN-SEQUENCE STARS). This also determines the main observational characteristics of the forming star, since it is shrouded in this material and hence predominantly radiates in the infrared.

As the main parts of the star come into hydrostatic equilibrium the simplified treatment of the 'standard' modelling becomes at least partly applicable. The energy output from the star comes predominantly from gravitational contraction, with half the gravitational potential energy released going to heat matter in the star and the other half being radiated from the surface. However, fusion of deuterium with ordinary hydrogen, which can take place at relatively modest temperatures, also plays a significant role. In the early parts of this phase the star is still relatively cold; as a result, the opacity is high and the star is completely convective. As discussed above, such stars are on the Hayashi track, moving down it with the continuing contraction.

With the increasing central temperature the opacity is reduced until the core regions of the star become convectively stable. As this region with radiative transport expands, the star moves away from the Hayashi track, towards higher effective temperature. During this phase, the evolution essentially follows the behavior given by equations (3) or (5). Finally the central temperature reaches a point where nuclear reactions may provide the required energy and the star settles down on the main sequence. As is clear from figure 3, this occurs in two steps for more massive stars: the initial step involves the fusion of ^{12}C and hydrogen, which occurs at a slightly lower temperature than the main processes of hydrogen fusion. After ^{12}C has been consumed the contraction continues until the main reactions start.

The time scale for these initial phases is essentially given by the Kelvin–Helmholtz time scale; for a $1M_\odot$ star evolution until the start of hydrogen burning takes around 50 Myr.

The onset of nuclear reactions requires that the central temperature reaches around 6 million K. In very low-mass objects this never happens: here matter becomes strongly degenerate and the thermal energy provided by the gravitational contraction is taken up by the degenerate electrons, rather than increasing the temperature. Such objects end up as *brown dwarfs* (see PLANETARY COMPANIONS AND EXTRASOLAR BROWN DWARFS), luminous because of the continuing contraction. The critical mass below which stable nuclear burning is not achieved is around $0.08M_\odot$.

Evolution on the main sequence

The evolution on the main sequence is driven by the gradual conversion of hydrogen to helium in the core of the star. This increases the mean molecular weight μ of the gas; to maintain the pressure, the density has to increase through contraction of the core, and this in turn causes an increase in temperature. As a result the rate of energy generation and the efficiency of radiative energy transport increase, causing an increase in the luminosity of the star; this is clearly visible in figure 1. Indeed, the increase in luminosity with increasing μ follows directly from equations (2) and (3).

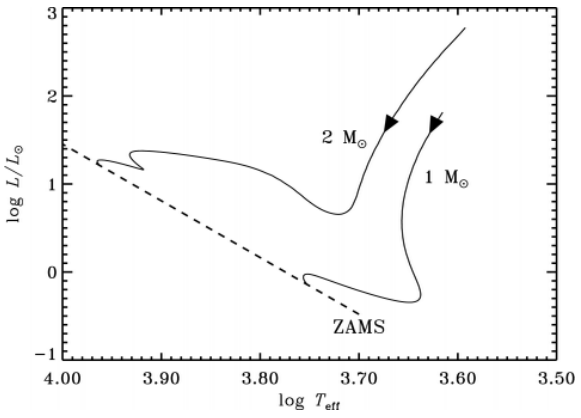

Figure 3. Pre-main-sequence evolution tracks for $1M_\odot$ and $2M_\odot$ stars. The initial evolution is down the Hayashi track but continues to higher effective temperature as a radiative core is established. The tracks end on the ZAMS where hydrogen fusion begins to contribute most of the stellar luminosity. (Data kindly provided by D A VandenBerg.)

In the case of the Sun, the luminosity has increased by approximately 30% from the ZAMS to the present. This change is sufficiently large to have substantial effects on the Earth's climate, unless other factors compensate; indeed, the effect has been known as 'the faint early Sun problem' and various attempts have been made to circumvent it. In fact, the luminosity increase is an essentially unavoidable consequence of the basic physics of stellar evolution, as is also suggested by the simple analysis above. Rather than tinkering with the stellar models, a far more likely solution to the problem would be changes in the Earth's atmosphere, e.g. such that the greenhouse effect was stronger in the past. Even so, it is interesting that feed-back mechanisms are apparently at work in the Earth's climate such as to maintain a nearly stable temperature despite the changes in solar radiation.

While the central parts of the star contract, the outer parts expand. This is visible from figure 1, using equation (4), by noting that the effective temperature remains constant or decreases while the luminosity increases. Such opposite behavior of the core and envelope of a star is a characteristic feature of stellar evolution, for which no satisfactory simple explanation seems to be available.

The details of the evolution on the main sequence, in particular how it ends, depend strongly on the mass of the star, as is also seen in figure 1. This is related to the possible presence of a convective core and its effects on the composition profile in the central parts of the star. Figure 4 shows the hydrogen abundance X by mass at various ages for stars of masses $1M_\odot$ and $2.5M_\odot$. In the $1M_\odot$ star the core is radiative and there is no mixing (within the assumptions of the 'standard' model). Hence the hydrogen abundance decreases most rapidly at the center, where the temperature is highest. When hydrogen is exhausted at the center, energy production still continues in a region immediately away from the center, and hence there is a gradual transition to the subsequent evolution phase, with fusion in a shell around a core consisting of helium and heavier elements. In contrast, the convective core in the $2.5M_\odot$ star is fully mixed on a time scale much shorter than the fusion time scale, and hence the hydrogen abundance decreases uniformly throughout the core. Although, as shown, the core generally shrinks with increasing age, hydrogen is essentially exhausted simultaneously throughout the central energy-producing region. In the final stages of central hydrogen fusion, the star contracts in an attempt to maintain the energy production by increasing the central temperature; this is visible in the evolution tracks in figure 1 by the left-ward 'hook', which is reminiscent of the earlier contraction phase before the main sequence (cf figure 3). Finally, as the central hydrogen is being totally exhausted, the star establishes a shell source around the helium core. The final evolution corresponding to the hook is rapid, compared with the preceding main-sequence evolution; thus few stars are found in this phase, as can be verified from observations of stellar clusters (see STAR CLUSTERS).

It is evident from figure 1 that the luminosity of the stars increases rapidly with stellar mass. This is consistent with equations (2) and (3). It also has dramatic implications for the time spent by the stars on the main sequence. Since the available nuclear energy is, approximately, proportional to the mass of the star, the nuclear lifetime scales as M/L or, according to the estimates of L, as M to an inverse power of at least 2. In fact, for stars of mass less that $0.9M_\odot$ the main-sequence lifetime exceeds the current age of the universe, while stars of more than $60M_\odot$ end their evolution in less than 4 million years.

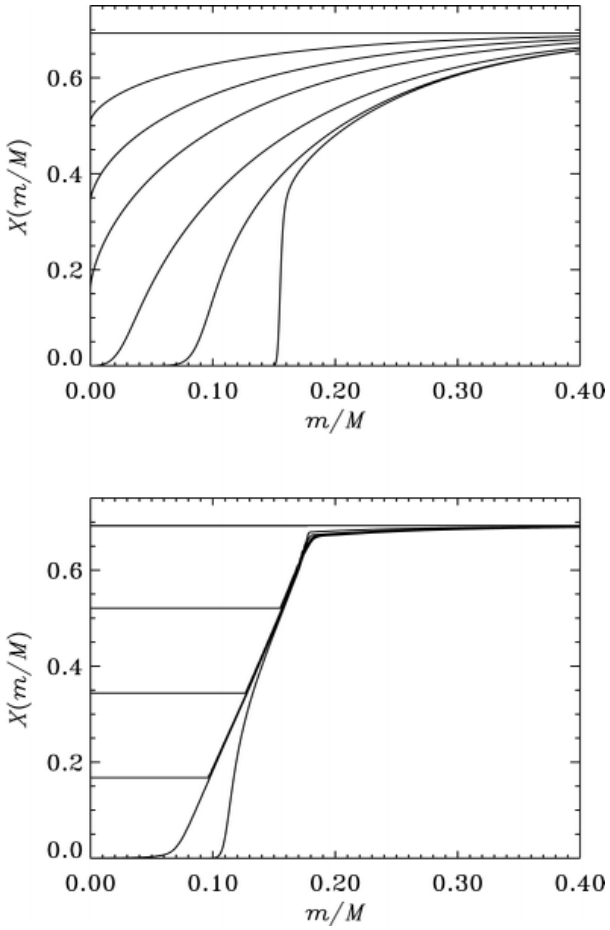

Figure 4. Evolution in the hydrogen abundance X by mass, as a function of time, against the fractional mass m/M in the star. The homogeneous initial models had $X = 0.692$. Top panel: $1M_\odot$, at ages 0, 2.47 Gyr, 4.53 Gyr, 6.49 Gyr, 9.29 Gyr, 10.81 Gyr and 11.62 Gyr. Lower panel: $2.5M_\odot$, at ages 0, 174 Myr, 306 Myr, 400 Myr, 462 Myr and 487 Myr.

Evolution after core hydrogen burning

After the end of central hydrogen fusion, the star has a helium core surrounded by a *shell source* where hydrogen fusion continues. As the shell source consumes hydrogen, the helium core grows and as a result contracts under gravity. This leads to heating of the core until the temperature is reached where the next fusion reaction, where three helium nuclei combine to form carbon, can take place. The star now has two sources of energy generation: the core helium fusion and the shell hydrogen fusion, with the latter generally supplying the larger part of the energy. This sets the pattern for the subsequent evolution and leads to what can be regarded as an onion structure of the star: central nuclear fusion alternating with core contraction and heating, and the establishment of shell sources outside regions where a given 'fuel' has been exhausted. An example of this structure is illustrated schematically in figure 5.

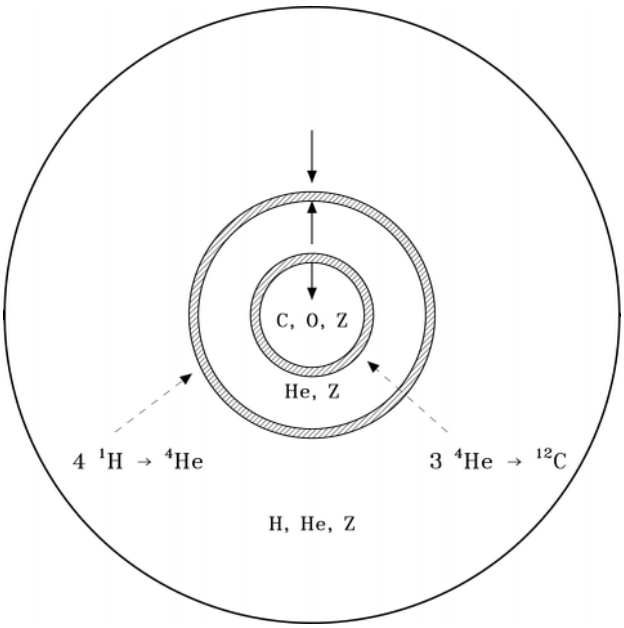

Figure 5. Schematic structure of a star with hydrogen and helium shell sources. The vertical arrows indicate the expansion or contraction of the corresponding regions. The thin hatched regions indicate the hydrogen- and helium-fusion shell sources.

The shell-burning 'law'

The behavior of the star during these changes in the core can to some extent be rationalized in terms of a simple principle, known as the 'mirror principle' or 'the shell-burning law'. This principle states that contraction or expansion reverses at a shell source: thus if the region inside a given shell contracts, the region outside the shell expands, and vice versa. No entirely satisfactory simple explanation has been given for this principle, but it is strikingly successful in explaining computed stellar evolution. It should be noticed that the same tendency for core contraction and envelope expansion was found during the main-sequence evolution phase.

The effect of this principle is immediately visible in the evolution tracks in figure 1. After the establishment of the hydrogen shell source, the contraction of the helium core leads to an expansion of the envelope; as the star is still predominantly radiative, luminosity and effective temperature are related by equation (3) or (5), and hence, with the expansion, the effective temperature decreases and the star moves towards the red-giant branch. When the star reaches the Hayashi track, a further decrease in $T_{\rm eff}$ would take the star into the 'forbidden' region on its cool side; since this is not possible, the continuing expansion takes the star up the red-giant branch. It is quite striking that these changes in the surface properties are essentially a reversal of the evolution before the main sequence. This phase continues to the point where the core temperature is sufficiently high for helium fusion to carbon to take place. In the solar case, that leads to a radius close to the radius of the Earth's orbit and a luminosity of approximately $2500L_{\odot}$.

The subsequent evolution depends rather sensitively on stellar mass. In many ways the intermediate-mass case is the simplest and is therefore considered first.

Later evolution of intermediate-mass stars

This covers stars in the mass range of roughly $(2–10)M_{\odot}$. An example of an evolutionary track is shown in figure 6. The evolution up to helium ignition follows the general description given above although the luminosity at the tip of the red-giant branch will not in general be as high as in the solar case. When helium fusion starts, the core expands as a result of the extra supply of energy. This expansion also helps stabilizing the temperature, such that helium fusion takes over in a controlled fashion. According to the shell-burning law, the core expansion leads to a contraction of the envelope, reflected in the evolution down the red-giant branch and later towards higher effective temperature. The relation between effective temperature and luminosity is again largely controlled by the usual relations, so evolution proceeds parallel to, although at a somewhat higher luminosity than, the earlier part of the track. In fact, during this stage the hydrogen shell source still contributes more than 70% of the total luminosity. With the continuing helium fusion, the core starts to contract again, and the envelope consequently expands, leading to evolution towards lower $T_{\rm eff}$.

This continues to the point where helium is exhausted in the core, which now consists of carbon, oxygen (also a product of the helium fusion) and heavier elements. As in the case of hydrogen, the core exhaustion of helium is followed by the establishment of a helium shell source. The situation is now as illustrated schematically in figure 5, with an inert and contracting

carbon–oxygen core. It is tempting to apply the shell-burning law to the *two* shells, as indicated by the arrows: the intermediate region might be expected to expand while the envelope of the star contracts. In fact, the expansion of the intermediate region leads to a reduction of the temperature in the region of the hydrogen shell source which therefore becomes inactive. At that point energy is provided essentially only by the helium-burning shell; the contraction of the core leads to a strong expansion of the envelope and the star moves back to and up the Hayashi track on the so-called *asymptotic giant branch*, to very high luminosity (cf. figure 6).

As the star evolves, the hydrogen shell is reactivated and takes over as the dominant source of energy. The subsequent detailed evolution is in fact complex, with developing thermal instabilities that cause both shell sources to be active in an oscillatory fashion. As shown in the insert in figure 6, this causes a large number of oscillations in the evolution track. The resulting changes in location of convective regions play an important role in the synthesis of the heaviest elements (beyond the iron group) through neutron capture and in bringing the products of these reactions to the surface of the star, where they can be observed as abundance anomalies.

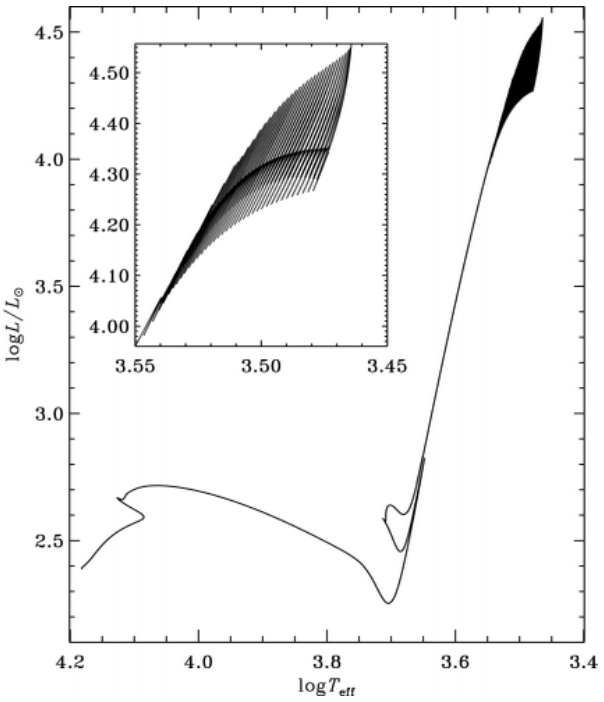

Figure 6. Evolution track for a $4M_\odot$ model, from the ZAMS to the asymptotic giant branch. As discussed in the text, the behavior in the diagram can be understood in terms of changes in the regions of nuclear energy generation. The insert shows the last phases in more detail, to illustrate the oscillations caused by the thermal instability between the hydrogen and helium shell sources. (Data kindly provided by A V Sweigart.)

An observation that three metal-poor stars are more rich in lead than in any element heavier than iron fits with the prevailing theory about the late, 'asymptotic giant branch' (AGB) phase of the evolution of stars 0.8–8 times the size of our Sun. It is thought that nuclei—mainly iron—deep inside an AGB star slowly capture neutrons, progressively building up heavier elements in what is known as the 's-process', which in the case of old stars will produce a pile-up of synthesized material with atomic weights between lead and bismuth. The new data (Van Eck *et al*) support this view, which hitherto had little observational support.

It might perhaps be expected that the further evolution would follow a pattern similar to the onset and development of helium burning, i.e. that the contraction of the core would lead to the ignition of the next nuclear reaction, fusion of carbon, followed by the establishment of yet another shell source. However, in this mass range the core never becomes hot enough for carbon fusion to start. There are two reasons for this. Firstly, the density of the contracting carbon–oxygen core becomes so high that the electrons become strongly degenerate; as in the case of low-mass pre-main-sequence stars this tends to limit the temperature increase, as the thermal energy obtained from the contraction goes into the degenerate electrons. Secondly, the core is cooled by various neutrino-generating processes in very dense plasmas; the neutrinos escape the core essentially unhindered, removing thermal energy.

The final stages of evolution for intermediate-mass stars are quite dramatic, although the underlying physics is poorly understood. The very extended outer envelope becomes unstable towards rapid mass loss, which over a period of probably less than 50 000 yr strips off essentially the entire envelope outside the carbon–oxygen core. That core remains behind as a very compact, degenerate object with a mass of $(0.5–1)M_\odot$ and a radius comparable with that of the Earth. It is initially extremely hot, with a surface temperature exceeding 100 000 K; it radiates predominantly by losing thermal energy, gradually cooling down. Such objects develop into white dwarfs. The matter ejected around the star shines for a few thousand years as a PLANETARY NEBULA, as a result of fluorescence caused by the ultraviolet radiation from the central object, before the matter is dispersed in the interstellar medium.

Later evolution of low-mass stars

For stars of mass below about $2M_\odot$ the onset of helium burning, at the tip of the red-giant branch, takes place in a rather more dramatic way than at higher masses. The main difference is that at lower masses the helium core is dominated by the pressure of degenerate electrons. The core is still heated, although mainly by the increasing temperature in the hydrogen shell source as it adjusts to

provide the high luminosity of the star. When the ignition temperature of helium (around 10^8 K) is reached, helium fusion starts, the release of energy causing an increase in the temperature of the gas. Since electron degeneracy dominates the pressure, it does not increase as a result of the temperature increase; this is unlike the situation in more massive stars, where the temperature increase causes an increase in pressure, which in turn leads to an expansion of the core and hence a stabilization of the burning. In the low-mass case, the temperature increase is not so controlled but rather leads to a further increase in the helium fusion rate and hence in the temperature. The result is a thermal run-away, in what is called *the helium flash*: during a few hours the rate of energy generation in the core reaches of order $10^{10}L_\odot$, comparable with the total luminosity of the Galaxy. This ends when the temperature of the core increases sufficiently that electron degeneracy becomes unimportant; at that point the core expands, reducing the temperature and stabilizing the burning.

The evolution of the outer parts of the star during the helium flash is rather uncertain. Most of the energy released during the flash is probably absorbed in an expansion or partial ejection of the already very extended envelope, on a dynamical time scale. When the star finally settles down to stable helium fusion, it is on the horizontal branch (see HORIZONTAL BRANCH STARS), at a position which probably mainly depends on the extent of the remaining hydrogen envelope.

The subsequent evolution is rather similar to that of the intermediate-mass stars discussed above; after completing central helium fusion, the star in general has both a hydrogen and a helium shell source, evolving through loops in the Hertzsprung–Russell diagram and finally up the asymptotic giant branch. During this phase of the evolution of the Sun, its radius is likely to exceed the radius of the Earth's orbit. As in the previous case, degeneracy and neutrino cooling prevent the core temperature reaching the values required for carbon fusion, and the star ends as a carbon–oxygen white dwarf, surrounded briefly by a planetary nebula.

Later evolution of high-mass stars

For masses higher than around $10M_\odot$ the core temperature after the end of helium fusion continues to rise, to a point where carbon fusion and later fusion reactions can take place. The end result is that the star ends its life in a supernova explosion (see SUPERNOVAE for further details).

The final series of nuclear reactions, starting with carbon fusion and leading up to the formation of a core consisting of iron-group elements, takes only a few hundred years, short even compared with the lifetime of massive stars. With the formation of the iron core the star has exhausted the possibilities of energy generation through nuclear processes: these elements have maximal nuclear binding energy, and further fusion would require energy. As a result, the core can only make up for its continuing energy loss through gravitational contraction; this causes further heating, to the extent that iron nuclei are dissociated to their basic constituents, protons and neutrons. The energy required for the dissociation further accelerates the contraction which takes the form of a dynamical collapse. With the increasing density, it becomes energetically favorable for the electrons to combine with the protons to form neutrons, with the emission of neutrinos. The collapse only halts when the core reaches nuclear densities and the neutrons become degenerate; the shock waves generated at the resulting sudden stop of the collapse, together with the neutrinos from the electron capture, transfer energy to the envelope which is ejected in the supernova explosion.

The energy powering the explosion comes entirely from the gravitational energy released in the collapse of the central $(1–2)M_\odot$ to a radius of around 10 km. In fact, the energy emitted in the form of light is only a small fraction of the total energy available; the largest fraction is taken up by the neutrinos emitted in the collapse.

The matter ejected in the explosion forms an interstellar gas cloud which is gradually dispersed (see SUPERNOVA REMNANTS). It is enriched by elements formed in the late stages of nuclear reactions, including rapid neutron capture during the explosion. The core of the star is left as an extremely compact object. If its mass is below $(1.5–2)M_\odot$ it forms a neutron star (see NEUTRON STARS), dominated by degenerate neutrons, and with a density corresponding to the density of nuclear matter. Such objects are observed as PULSARS. If the core is more massive, even the pressure from the nuclear matter cannot resist gravity, and the core collapses to form a BLACK HOLE.

Tests of stellar evolution

The evolution sequences presented above provide a detailed history of stars, solidly founded in the 'standard' theory of stellar evolution. However, *testing* these results in detail is difficult. Helioseismology has provided very detailed inferences of the solar internal structure, which are generally well matched by the models. Similarly detailed information is entirely out of reach for distant stars, whose surfaces, even with planned space experiments, will only be resolved to a limited extent. On the other hand, studies of a broad range of stars allow tests of our understanding of stellar evolution under conditions far more extreme than found in the Sun and including phenomena, such as convective cores, which are not relevant in the solar case.

Substantial efforts are being invested in asteroseismic investigations of stars, using oscillation frequencies to probe stellar interiors. Detailed

information has been obtained in the case of white dwarfs, leading to accurate determinations of their masses, as well as estimates of the thickness of the outer hydrogen and helium layers. Studies of double-mode Cepheids demonstrated gross errors in the opacity tables, subsequently confirmed by improved opacity calculations; this has led to substantial revisions also of other aspects of stellar modelling. For other types of stars, data on oscillation frequencies are being accumulated, although uncertainties in the mode identification have so far precluded their use for detailed studies of stellar interiors. This is likely to change with the ongoing and planned observational and theoretical efforts, including observations from space. In 2001, solar-like oscillations in the stars beta Hydri and alpha Centauri A were detected.

More classical observations have also provided stringent tests of stellar-evolution calculations, at least as far as the global properties of the stars are concerned. Particularly important are observations of binary stars in eclipsing variables, where accurate determinations of the stellar masses and radii are possible (see ECLIPSING BINARY STARS). This, together with the highly probable assumption that the stars have the same age and original chemical composition, places strong constraints on the stellar models.

In almost all cases the relevant time scales are too long to allow direct observation of the consequences of stellar evolution. However, a powerful alternative is provided by observing ensembles of stars of the same age but different masses: since the evolution time scale varies strongly with mass such a collection of stars contains stars in a broad range of evolutionary stages. Such ensembles are provided by star clusters, collections of stars that are clearly physically associated. It may generally be assumed that the stars in a cluster were formed from the same interstellar cloud at approximately the same time. Thus they have a common age and original chemical composition, while differing in mass. Furthermore, all stars in a cluster are at approximately the same distance. Thus the correction from the true luminosity of the stars to the apparent luminosity at the (generally *a priori* unknown) distance of the cluster is the same for all the stars.

The observed distribution of stars in a cluster can be compared directly with computed *isochrones*, i.e. curves corresponding to models of the same age but different mass. This comparison also provides an estimate of the age of the cluster; furthermore, the shift between the computed luminosity and the observed apparent luminosity of the main-sequence stars is a measure of the distance to the cluster. An interesting example, for the globular cluster M92, is illustrated in figure 7. The distribution of observed stars clearly reflects the evolutionary pattern: stars of the lowest masses are still on the main sequence, with core hydrogen burning. Somewhat more massive stars, where hydrogen is exhausted at the center, occupy the subgiant branch, starting at the turnoff, and the red-giant branch, whereas the stars originally of the highest mass have gone through a helium flash and are found on the horizontal branch or, in a few cases, at the beginning of the asymptotic giant branch. The very large number of stars in a globular cluster ensures that all stages of evolution are well represented. Computed isochrones are shown for a few ages, a reasonable fit being obtained for an age of 14 Gyr (the shift of the red-giant branch relative to the observations may be due to an error in the atmosphere models used to calibrate the models from effective temperature to color index). It is remarkable that the inferred age is rather larger than some values of the estimated age of the universe, as obtained from cosmological measurements. This problem suggests serious deficiencies in either the commonly used cosmological models or in the calculation of stellar models.

A second example, for the open cluster NGC 3680, is shown in figure 8. In this case, the cluster has been strongly affected by dynamical evolution, leading to very substantial loss of stars (furthermore, in the analysis care was taken to include only single stars that definitely belong to the cluster); as a result the diagram is sparsely populated, compared with figure 7. Two isochrones are shown: one for a 'standard' evolution calculation and the second for models including penetration and mixing from the convective cores (see below). There is clearly strong evidence that the models with such additional mixing provide the better fit to the observations.

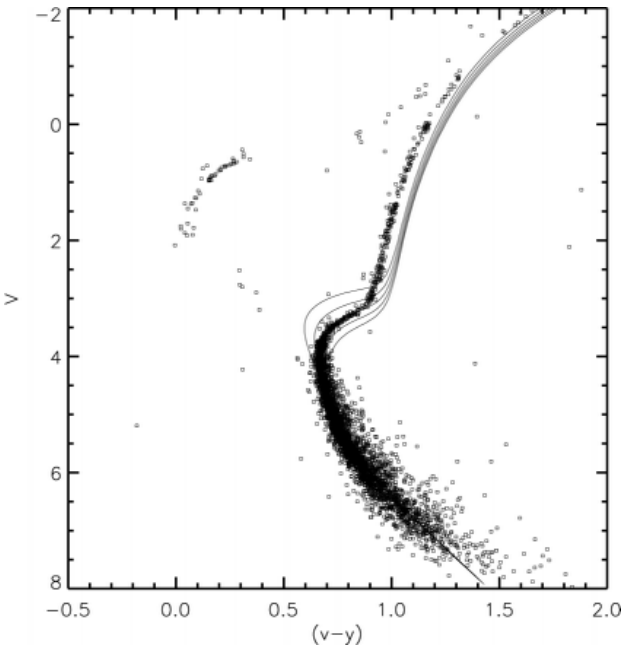

Figure 7. Hertzsprung–Russell diagram for the globular cluster M92. The abscissa is color index (in the Strömgren system), which provides a measure of the effective temperature, whereas the ordinate is apparent magnitude. The curves show isochrones corresponding to ages (from the top) of 10, 12, 14, 16 and 18 Gyr. (Kindly provided by F Grundahl.)

Beyond the 'standard' model

Although the analysis of stellar evolution, as presented here, is quite successful in rationalizing many observed properties of a wide range of stars, its intrinsic simplifications should be kept in mind. A few examples will be considered here.

Mass loss undoubtedly plays a very important role in many phases of stellar evolution. This has already been mentioned in connection with asymptotic-giant-branch stars, where rapid mass loss is observed and must presumably be involved in the formation of planetary nebulae and white dwarfs. Lower-mass main-sequence stars also show mass loss as in the solar wind (see SOLAR WIND: GLOBAL PROPERTIES) although probably not at a rate that substantially affects stellar evolution. However, in high-mass stars, the very strong radiation field seems to drive quite strong stellar winds, which are probably implicated in the formation of WOLF–RAYET STARS.

The hydrodynamics of stellar interiors is treated in a very simple manner in normal stellar-evolution calculations, yet could have important effects. The most important problems concern mixing of otherwise chemically inhomogeneous regions of the star. For example, there is little doubt that motion extends beyond the convectively unstable regions, in the form of convective penetration into the stable regions and possibly internal gravity waves induced by such penetration. This would cause mixing outside convective cores and hence would increase the amount of hydrogen available for fusion as well as the extent of the helium core left after the end of core hydrogen fusion; yet the extent of such penetration is highly uncertain. In stars above about $10M_{\odot}$, additional uncertainties are introduced by possible instabilities outside convective cores which may lead to the so-called *semiconvection*, probably causing additional mixing.

Stars are observed to rotate, often rapidly (see STELLAR ROTATION ON THE MAIN SEQUENCE), yet most evolution calculations ignore rotation. Rapid rotation deforms the star, with direct effects on its structure. However, even slow rotation may cause circulation (the so-called *Eddington–Sweet circulation*) which could cause mixing, and gradients in the rotation rate could lead to hydrodynamical instabilities that might also mix the material. Particular problems are related to the slowing down of rotation in low-mass stars from a likely state of initial rapid rotation, probably as a result of angular-momentum loss from the outer parts of the star in a magnetic stellar wind; this has at least in the solar case led to roughly uniform rotation of the solar interior (see SOLAR INTERIOR: ROTATION). However, the mechanisms coupling rotation of the deep solar interior to the surface, and their possible effects on other aspects of stellar evolution, are not understood.

Evolution in close binary systems adds a great deal of complication to this already complex situation (see CLOSE BINARY STARS). As the more massive of the two components evolves and expands, possibly reaching the red-giant stage, mass transfer to the other component, or mass loss from the system, may take place. This in turn causes changes in the orbital parameters of the system. With continuing evolution, mass may be transferred back and forth between the components, greatly affecting their evolution. The detailed behavior evidently depends sensitively on the initial parameters of the system. Mass transfer, particularly onto compact objects such as white dwarfs and neutron stars, also gives rise to spectacular observational phenomena (see CATACLYSMIC BINARIES). In particular, the so-called supernovae of type Ia are believed to occur when white dwarfs become unstable after accretion of matter from a companion star.

Acknowledgments

I am very grateful to J Lattanzio and A V Sweigart for illuminating discussions on late stellar evolution and to Sweigart, J Andersen, F Grundahl and D A VandenBerg for providing data for figures. I thank the many authors who have kindly provided drafts of their articles, which have substantially assisted the writing of this article.

Stellar Interiors

The subject of stellar interiors is concerned with the determination of the run of density, temperature, luminosity (the energy flow rate through a closed three-dimensional surface) and composition from the center to the surface of stars. The determination of these quantities requires the solution to the conservation laws of mass, momentum and energy at each point in the model. These conservation laws have terms which directly include the pressure of the material and the energy produced by nuclear reactions in the interior. In order to fully solve the energy conservation equation, a relationship between the thermal structure and the energy transport must also be specified. The relationship will be different for each of the three mechanisms—radiation, convection and conduction. From the density, temperature and composition, the pressure may be determined from atomic physics, the rate at which nuclear energy is generated from nuclear physics and the mode of energy transport and its efficiency from atomic (radiation) and classical (convection) physics.

The form that conservation of momentum takes in most stars is defined by the concept of hydrostatic equilibrium. Hydrostatic equilibrium is the condition that forces at all locations inside a star just balance. Most commonly, these are the internal pressure forces balancing the self-gravitational forces of the stellar material. Most stars satisfy hydrostatic equilibrium to a great degree, although there are stars which oscillate about hydrostatic equilibrium (pulsating stars), and stars that are either collapsing or exploding are far removed from hydrostatic equilibrium. Significant departures from hydrostatic equilibrium occur on the free fall time, which is generally so short (about an hour for the Sun) that they are readily observable.

The relationship between the density, temperature, composition and pressure is called the equation of state, and its functional form is quite different in different temperature–density regimes. For stars on the main sequence, those stars which are converting hydrogen to helium at the very center of the star, the relation is that of an ideal gas pressure produced by the motion of the nuclei and free electrons plus the radiation pressure produced by the photons. As stars evolve both the central density and the central temperature increase, and there may be other contributors to the equation of state. For densities that are sufficiently high (how high depends on the temperature), the pressure may be supplied by degenerate electrons, which are governed by the Pauli exclusion principle which holds that identical fermions cannot be too close together. The resistance of the identical electrons to being squeezed together provides the pressure. In very late stages of stellar evolution, at much higher densities, the pressure may be supplied by degenerate neutrons for the same reason.

Although the focus here has been on the pressure, rotation and magnetic fields also provide forces which should be included in hydrostatic equilibrium, but generally are not because they are generally of secondary importance and they complicate the mathematical problem significantly.

The conservation of energy requires that the amount of energy produced inside a volume equals the net amount of energy flowing out of the volume. This requires knowledge of nuclear reaction rates to determine the energy produced and knowledge of the energy transport mechanism to determine the energy transport. The energy-producing reactions for most stars are fusion reactions combining light nuclear species into heavier nuclear species, which occur in the deep interior. As the star ages it first converts hydrogen into helium at the center on the main sequence and then in a shell about a hydrogen-depleted region as a subgiant and then a RED GIANT STAR. The hydrogen burning may occur in either of two ways. The first, called the p–p chain, starts with two protons reacting, while the second, the CNO cycle, starts with a proton reacting with a carbon nucleus. The net effect of both is to convert four protons into a helium nucleus and an array of other particles and radiation. The next evolutionary phase converts three helium nuclei at the center into carbon by the triple alpha process, and other more complex reactions follow. The evolution of the composition causes the internal structure of the star to change, and the star is said to evolve (see STELLAR EVOLUTION). This evolution is said to occur on a nuclear timescale, which is dependent on the rate of change of the composition in the nuclear burning regions. During transitions from one set of nuclear processing reactions to another, the star may have to undergo some structural readjustment via slow gravitational contraction or expansion, on a timescale called the Kelvin–Helmholtz time, in order to create the necessary conditions for the next nuclear processing sequence to begin.

The energy generated by nuclear reactions will clearly depend on the number of the available reactants, the energy produced by the nuclear reaction and the cross section which indicates the likelihood that the reaction between the two nuclei takes place. In stellar interiors the relative motion between the interacting nuclei is provided by thermal motion, while experimentally this is provided by accelerating one of the nuclei to high velocity where it hits a stationary target of the other nucleus. The relative motion is much larger in our experiments than in stars, and the cross sections determined must be extrapolated to lower energy for stellar conditions. It can be shown that the thermal energies are not sufficient to overcome the Coulomb repulsion between two positively charged reactants, but one nucleus can 'tunnel' beneath the potential because of the small quantum mechanical probability of the nucleus penetrating the Coulomb barrier of the other. The nuclear reaction cross section may also be greatly enhanced by the presence of resonances produced by the nature of the wavefunction inside and outside the Coulomb barrier. For more information, see NUCLEOSYNTHESIS and NUCLEAR REACTION RATES.

The nuclear energy generation rates are very strong functions of the temperature. If we express the energy

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

generation rate as a power law in the temperature over a limited range of temperature, we find that the power for the p–p chain is 4–6, depending on the temperature, about 16 for the CNO cycle and approximately 30 for the triple alpha process.

The other component of the energy equation is the transport. Radiative transport in the deep interior of a star is relatively simple, primarily because the distance any photon can travel, its mean free path, is very short compared with the distance for a significant temperature gradient to occur. Thus all the matter and all the photons in a volume whose size is determined by the photon mean free path have essentially the same temperature. This is one description of a black body, for which the radiation field is homogeneous and isotropic and the intensity is given by the Planck function, B_ν. We start with the first-order moment of the radiative transfer equation by multiplying the transfer equation by the cosine of the angular variable and integrating over all angles to obtain (see RADIATIVE TRANSFER),

$$H = \int H_\nu \, \mathrm{d}\nu = -\int \frac{1}{\kappa_\nu} \frac{\mathrm{d}K_\nu}{\mathrm{d}z} \, \mathrm{d}\nu \equiv -\frac{1}{\kappa_R} \int \frac{\mathrm{d}K_\nu}{\mathrm{d}z} \, \mathrm{d}\nu$$

where H is proportional to the energy flux and K to the radiation pressure. The isotropic nature of the Planck function allows the intensity to be factored out of the angular integrals, so that $K_\nu \rightarrow \frac{1}{3} B_\nu$. Since the Planck function is only a function of temperature, we may write $\mathrm{d}K_\nu/\mathrm{d}z = \frac{1}{3}\,\mathrm{d}B_\nu/\mathrm{d}z = \frac{1}{3}\,(\mathrm{d}B_\nu/\mathrm{d}T)\,\mathrm{d}T/\mathrm{d}z$. Substitution defines a calculable quantity, the Rosseland mean opacity (κ_R)

$$\frac{1}{\kappa_R} = \int \frac{1}{\kappa_\nu} \frac{\mathrm{d}B_\nu}{\mathrm{d}T} \, \mathrm{d}\nu \Bigg/ \int \frac{\mathrm{d}B_\nu}{\mathrm{d}T} \, \mathrm{d}\nu$$

and an expression for the total flux:

$$H = -\frac{1}{3} \frac{1}{\kappa_R} \frac{\mathrm{d}B}{\mathrm{d}T} \frac{\mathrm{d}T}{\mathrm{d}z}.$$

From this last expression, called the diffusion approximation, one can see the relationship between radiative transport and a normal thermal conductivity. A similar expression to the above can be derived for thermal conduction, which is important only when degenerate conditions exist. The total flux would be the sum of the radiative and conductive fluxes, so that the total opacity is the harmonic mean of the radiative and conductive opacities. Note that the Rosseland mean opacity conserves the total flux and gives the greatest weight to those frequencies where the opacity is lowest. The diffusion approximation does not hold in the optically thin upper region of the stellar envelope, and it is strictly speaking necessary to use a different formulation to obtain the temperature stratification (although this is not always done). Generally, the logic is that the stellar structure and evolution can be determined quite well even when the surface is treated somewhat cavalierly.

Convection poses a significant challenge to our knowledge of stellar structure. However, convection is very important because it is expected that the composition is uniformly mixed in a convection zone, so that convection is an important mechanism for transporting material that has been processed by nuclear reactions deep inside a star to other locations. Indeed, current theoretical and observational results indicate that there is some mixing of material beyond the formal boundary of a convective region. This is important from an evolutionary point of view, because it means that material is mixed into the convective core from just outside it and thus is processed by nuclear reactions. This prolongs the lifetimes during these phases of evolution. In the core, the expectation is that the convective efficiency is so great that the relationship between the density, temperature and pressure is adiabatic.

In the layers near the stellar surface, the convective efficiency will not be very great because the material densities are so low, and a relatively simple mixing length formalism has traditionally been used to determine the convective structure. This model has one major free parameter, the mixing length, which governs how far a convective element will travel before depositing its energy in the surrounding medium. As might be imagined, the farther the element travels, the more efficient the convective transport. The major effect of uncertainties in the convective envelope structure is uncertainty in interpretation of stellar properties such as the stellar radius and the relationship between the observed color and the effective temperature.

This simple model continues to be used because no alternative model or method with more tightly constrained free parameters has been able to demonstrate that it yields answers that agree more closely with observations. These alternative models may be crudely classified into two categories—analytical one-dimensional models which are meant to be incorporated into the traditional one-dimensional methods of solution (see below), and models which are based on multidimensional hydrodynamical simulations of astrophysical convection. These are not mutually exclusive, as there are analytical models which have been based on the results of multidimensional hydrodynamic simulations.

Multidimensional simulations of turbulent convection are not trivial. In a simple-minded picture of turbulence, convective motion is produced on the largest scales (here presumably the size of the convection zone) and cascades down to progressively smaller scales until the scale is sufficiently small that the viscous forces convert the kinetic energy of the convective motion into heat. In stars, the size of the convection zone can be very large, something on the order of a typical stellar radius (10^{11} cm for an order of magnitude), while the length scale on which the viscosity can convert the kinetic energy into heat may be seven orders of magnitude smaller. Trying to resolve all of these length scales in hydrodynamic calculations is beyond the capabilities of current computers and likely to

remain that way for some time. The general approach for hydrodynamic simulations is to divide the calculation into two components—that which can be spatially resolved and that which cannot. The first is directly included in the solution of the appropriate equations, while the terms involving the second must be approximated by models which contain only the spatially resolved component. This has been done in many ways, and much work remains to translate these results into something that can be used to determine the structure in general stellar situations. For more discussion, see STELLAR INTERIORS: THERMODYNAMICS.

Supposing it possible to calculate the interior structure for a model of stipulated mass and composition, what techniques are available to determine whether the model bears any resemblance to a given observation? The answer is qualified by what is known about the star. From the spectral energy distribution and absorption line strengths of the light emitted from the stellar surface, we can obtain an estimate of its effective temperature, surface gravity and surface composition. Information about the interior may be gained in some cases from elements which have been processed in the interior and mixed to the surface. For example, the amount and the isotopes of lithium and beryllium, which capture protons at relatively low temperatures, indicate whether the surface convection zone has penetrated to such temperatures at some time in the past. If we have some method of determining the star's distance, we can obtain its luminosity, and we can determine its mass if it is in an eclipsing binary system.

Clusters (see STAR CLUSTERS) provide an opportunity to obtain more information. Clusters are groups of stars which formed at nearly the same time out of material with nearly the same composition. Thus, the stars in a cluster provide a sequence of stars whose primary difference is the stellar mass. Combining a number of stellar model calculations of stars with the same initial composition and age but different masses allows comparisons with the HR diagrams (plot of luminosity versus effective temperature—see HERTZSPRUNG–RUSSELL DIAGRAM).

The Sun presents a special case because of its proximity and thus the level of detail we can detect. Detected neutrinos from the Sun should yield information about the structure of the solar center, but models have not yet been able to produce the observed neutrino flux while matching all the other available solar data (see SOLAR INTERIOR: NEUTRINOS).

We also observe a very large number (about 10^5) of low-amplitude pulsation modes believed to be powered by the solar turbulent convective envelope. These periods convey information about the sound travel time from the surface to a depth which depends on the mode, with longer-period pulsation modes 'sounding' to greater depths. Thus the period difference between two modes which are very close in period, and thus penetrate to nearly the same depth, contains information about the sound speed in the region between the effective depths of the two modes. This is similar to seismic waves sampling different depths inside the Earth, leading to this study of the Sun being termed HELIOSEISMOLOGY. With the many modes available, the sound speed, and hence the internal structure, has been observationally determined for the outer 80% of the solar radius. From this structure, we can determine the depth of the surface convection zone, a constraint that any convective model must match. Furthermore, by examining modes which are effectively the same radially but differ horizontally, the solar rotation rate as a function of depth and solar latitude can be determined to the same depth.

The major surprises resulting from this comparison were that the solar convection zone extended to greater depth (about the outer 30% of the radius) than previously thought and that the solar rotation rate in the convective envelope is approximately proportional to the radius with different coefficients at different latitudes. The depth of the convection zone is matched by increasing the value of the mixing length to something like 1.7 pressure scale heights (the precise value depends on the mixing length formulation used) from the previously traditional range of 1.0–1.5 pressure scale heights. Current solar models provide agreement with the sound speed data to within a few tenths of a per cent, while models before helioseismology are now known to be about 1.5% in error.

Can such an approach be extended to other stars (asteroseismology)? The obstacles are formidable because of the distance to other stars. The most promising stars would appear to be δ Scuti variable stars, white dwarfs, and perhaps high-mass stars near the main sequence. However, no other star currently has more than 200 modes known, and our less detailed knowledge about any given star makes mode identification much more difficult than for the Sun.

We now turn to a more detailed discussion of how the interior structure of a model is calculated and some simple models.

The equations of stellar structure

We begin with the conservation of mass and the conditions of hydrostatic equilibrium (excluding all forces but self-gravity and the internal pressure) and thermal equilibrium for spherically symmetric models:

$$\frac{\mathrm{d}M_r}{\mathrm{d}r} = 4\pi r^2 \rho \qquad \frac{\mathrm{d}P}{\mathrm{d}r} = -\rho \frac{GM_r}{r^2} \qquad \frac{\mathrm{d}L_r}{\mathrm{d}r} = 4\pi r^2 \rho \varepsilon$$

where M_r is the mass interior to radius r, ρ is the density, P is the pressure, L_r is the luminosity flowing through radius r and ε is the nuclear energy generation rate. Both the pressure and the nuclear energy generation rate are expressed as functions of the density and temperature for a given composition. Assuming the composition is stipulated *a priori*, we see that we have three equations with the four unknowns (ρ, T, M_r and L_r). The missing equation is one relating the thermal structure to the energy transport. Writing $\nabla = \mathrm{d}\ln T/\mathrm{d}\ln P$, we have three possibilities for this equation:

$$\nabla = \nabla_{rad} = \frac{3\kappa P L_r}{16\pi acGT^4 M_r}$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

$$\text{radiative, conductive,} \nabla_{rad} < \nabla_{ad}$$

$$\nabla = \nabla_{ad} \qquad \text{efficient convection,} \nabla_{ad} < \nabla_{rad}$$

or

$$\nabla = \nabla_{act} \qquad \text{inefficient convection,} \nabla_{ad} < \nabla_{act} < \nabla_{rad}.$$

The first equation is used in the convectively stable ($\nabla_{ad} > \nabla_{rad}$) region where the energy is carried by radiation or conduction or both, the second in convectively unstable ($\nabla_{ad} < \nabla_{rad}$) deep layers where the convection is so efficient that the structure may be taken to be adiabatic and the third in convectively unstable regions where the convection is inefficient and the gradient is supplied by some convective transport algorithm such as the local mixing length theory.

These equations then determine the stellar structure. However, they are usually not solved in this form, because the radius is generally not the most useful independent variable. Rather, the independent variable is taken as the interior mass, M_r. One obtains the equations in terms of this variable by solving for dr in the mass conservation equation and substituting this in the other equations to obtain derivatives with respect to M_r. Since there are four first-order differential equations, we require four boundary conditions. At the stellar center, the values of M_r, r and L_r are zero. The conditions at the stellar surface have a little more latitude. The density and pressure are so low compared with those at the stellar center that $P = \rho = 0$ (called the zero boundary conditions) are often a good approximation. More sophisticated techniques use stellar atmosphere models to fit all variables (i.e. ρ, T, r and L_r) at a given location (i.e. M_r) below the stellar surface.

Most determinations of stellar interior conditions are now made with computational numerical models, but some historical and somewhat instructive analytical models were developed before extensive numerical simulations became possible.

Simplified models

Before numerical computers it was necessary to simplify the stellar structure equations to obtain either analytical solutions or solutions which required only a limited amount of calculation. The simplest of these approaches is for a polytrope, which is defined by the relation $P = C\rho^{(n+1)/n}$. Thus, one may write $P = P_c\theta^{n+1}$ and $\rho = \rho_c\theta^n$. To obtain an equation utilizing this definition, divide the hydrostatic equilibrium equation by $r^2/\rho G$, take the derivative with respect to r and use the mass conservation equation to obtain

$$\frac{\mathrm{d}}{\mathrm{d}r}\left(\frac{r^2}{\rho G}\frac{\mathrm{d}P}{\mathrm{d}r}\right) = -\frac{\mathrm{d}M_r}{\mathrm{d}r} = -4\pi r^2\rho.$$

With the above definition for θ, this becomes

$$\frac{(n+1)P_c}{4\pi G\rho_c^2}\frac{1}{r^2}\frac{\mathrm{d}}{\mathrm{d}r}\left(r^2\frac{\mathrm{d}\theta}{\mathrm{d}r}\right) = -\theta^n.$$

This equation may be simplified by introducing a length scale, r_s, by $r = r_s x$. Defining

$$r_s^2 = \frac{(n+1)P_c}{4\pi G\rho_c^2}$$

leads to the Lane–Emden equation

$$\frac{1}{x^2}\frac{\mathrm{d}}{\mathrm{d}x}\left(x^2\frac{\mathrm{d}\theta}{\mathrm{d}x}\right) = -\theta^n.$$

From the definition of θ, $\theta = 1$ at $x = 0$. Also, spherical symmetry requires that $\mathrm{d}\theta/\mathrm{d}x = 0$ at $x = 0$. The surface boundary conditions ($P = \rho = 0$) are met at x_1 where $\theta(x_1) = 0$. Clearly, both P and ρ must be positive, so that x_1 corresponds to the first zero of θ. The attractiveness of this equation is apparent in the need to solve the Lane–Emden equation only once for a given n, a tedious but performable task. There are analytical solutions for $n = 0$, 1 and 5, and there are published tables of $\theta(x)$ for $1 \leq n \leq 5$ in steps of 0.5. Once P_c and ρ_c are selected and $\theta(x)$ is computed, one may solve for P, ρ, M and R.

The advantage of polytropes from a computational point of view is undeniable, especially when calculations had to be done by hand or with mechanical calculators. However, do polytropes ever resemble real stars? More specifically, are there situations in which a combination of the equation of state and the structure required by energy transport produces a polytropic relation?

The most noteworthy case for which polytropes resemble real stars is for white dwarfs. If the electrons are fully degenerate throughout the entire white dwarf, the degenerate equation of state requires a polytropic structure with $n = 1.5$ if the electrons are non-relativistic and $n = 3$ if they are extremely relativisitic. With the temperature absent in the equation of state, hydrostatic and thermal equilibria decouple. The hydrostatic structure is that of a polytrope, while the thermal structure is determined by the thermal structure when the star became a white dwarf and its cooling as the thermal energy is transported to the surface and radiated. Chandrasekhar was thus able to demonstrate that degenerate electrons allowed the possibility of stars with a solar mass of material inside a volume about that of the Earth and, furthermore, that there was an upper limit to the mass allowed for a white dwarf.

While less dramatic than the theoretical possibility of white dwarfs, both fully convective stars and parts of other stars resemble polytropes. The chief virtue of the latter is a variety of models in which the solution for the stellar structure is somewhat less laborious than for the full stellar structure equations.

With the current environment in which it seems that there is a computer on every desk, these models are of limited interest, and the methods by which stellar structure is currently calculated are now examined.

Numerical solution of the stellar structure equations

Once sufficient computing power became available, it became possible to develop numerical algorithms to

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

solve the equations of stellar structure using with either numerical tables or analytical fits to describe the equation of state, opacity and nuclear reaction rates. There have been two numerical algorithms which have been used successfully, a fitting technique and an implicit finite difference method. Current calculations are dominated by finite difference techniques.

The simple reason why one cannot use ordinary integration techniques, such as the Runge–Kutta method, is that the boundary conditions are divided between the surface and the center of the stellar model. The fitting technique tries to remove this problem by making plausible assumptions for the conditions one does not know, say the central density, central temperature (or equivalently central pressure), surface luminosity and surface radius, and integrating from both the model center and the model surface and meeting at some interior location (the fitting point, call it M_{r0}). If all the selections for the four unknowns were correct, the temperature, density, luminosity and radius from the two integrations would agree at M_{r0}. Thus, we have four conditions which must be satisfied and four unknowns, so the problem in principle can be solved. The problem can be simplified slightly by choosing M_{r0} to be exterior to the energy generation region, performing the core integration first and using the luminosity at M_{r0} as the guess for the surface luminosity.

In practice there are some difficulties. One is that the guesses for the central unknowns must be fairly good or the integration may not even reach M_{r0}. Another is that we have not considered the possible composition variations, whose values at any given location may depend on whether it is in a thoroughly mixed and therefore uniform composition convective region and how much mass the convective region may contain (and which for convective cores may not be known until the convective core boundary is reached in the outward integration from the center). Thus, the fitting technique is now used primarily for determining a guess for a uniform composition zero-age main sequence model.

The finite difference approach divides the stellar model into a finite number of discrete zones and replaces the first-order differentials by differences between two adjacent zones. The model is then determined by evaluating these finite difference equations in all zones along with the boundary conditions for all the variables in all the zones.

The Henyey method is the most common way these solutions are generated. For simplicity, suppose that there is only one second-order differential equation to be solved with the form

$$f(x, y) = \frac{\mathrm{d}^2 y}{\mathrm{d}x^2} + g(y, x)\frac{\mathrm{d}y}{\mathrm{d}x} + h(y, x) = 0.$$

The second-order differential means that the finite difference representation involves values of y in three adjacent zones. Assume that there is a guess for the solution $y(x)$ of this equation, then perturb the guess and keep only the linear term in the perturbations (δy). For each zone, i, there will be an equation of the form

$$A_i\,\delta y_{i-1} + B_i\,\delta y_i + C_i\,\delta y_{i+1} + D_i = 0.$$

D_i is the value of the function f evaluated in zone i with the current guess and

$$A_i = \frac{\partial f}{\partial y_{i-1}} \qquad B_i = \frac{\partial f}{\partial y_i} \qquad C_i = \frac{\partial f}{\partial y_{i+1}}.$$

Note that as D approaches zero for all i, all the δy_i go to zero as well. Suppose that there is one boundary condition at the center of the stellar model ($i = 1$) and one at the surface ($i = n$). The central boundary condition may be used to eliminate δy_0 from the equation for $i = 1$, and the surface condition to eliminate δy_n from the equation for $i = n$. Thus, the difference equations will have the form

$$B_1\,\delta y_1 + C_1\,\delta y_2 + D_1 = 0$$

$$A_i\,\delta y_{i-1} + B_i\,\delta y_i + C_i\,\delta y_{i+1} + D_i = 0 \qquad i = 2, \ldots, n-1$$

$$A_n\,\delta y_{n-1} + B_n\,\delta y_n + D_n = 0.$$

For $i = 1$, it is possible to write

$$\delta y_1 = \alpha_1\,\delta y_2 + \beta_1$$

where

$$\alpha_1 = -B^{-1}C_1 \qquad \beta_1 = -B^{-1}D_1.$$

Substituting these expressions into the equation for $i = 2$ leads to

$$A_2(\alpha_1\,\delta y_2 + \beta_1) + B_2\,\delta y_2 + C_2\,\delta y_3 + D_2 = 0.$$

Combining terms and using the definition of α and β for $i = 2$, one obtains

$$\alpha_2 = -(A_2\alpha_1 + B_2)^{-1}C_2 \qquad \beta_2 = (A_2\alpha_1 + B_2)^{-1}(A_2\beta_1 + D_2).$$

Continuing this exercise for all zones generates a set of recursion relations for the α and β. One virtue of these relations is that generally the α_i are of order unity, which tends to eliminate mathematical errors when the various terms have much different orders of magnitude.

The result for $i = n$ is

$$(A_n\alpha_{n-1} + B_n)\,\delta y_n + A_n\beta_{n-1} + D_n = 0$$

so that

$$\delta y_n = -(A_n\alpha_{n-1} + B_n)^{-1}(A_n\beta_{n-1} + D_n).$$

From this all the other δy_i can be found from the relations defining the α_i and β_i.

Finding the δy_i obtains the solution of the best linear correction to solving the equation. However, the corrections may be so large that dropping the higher-order corrections is unwarranted. The whole process is therefore repeated until all of the corrections are below some desired

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

tolerance. Because the lowest omitted term is of order δy^2, convergence is quadratic.

Furthermore, there is nothing limiting about having only one equation with one independent variable. If there are several (N) differential equations ($f_1, \ldots, f_N$) with the dependent variables ($q_1, \ldots, q_N$), the same methodology can be used. The A, B, C and α now become N by N matrices, and the D, β and δy become column vectors of length N.

Unresolved issues in stellar structure

With these methods models of stellar structure can be generated routinely. Yet even after many models our knowledge of stellar interiors is incomplete. There are significant disagreements over elements that are produced in the interiors of some stars and mixed to the surface which models do not predict. Other issues are the times some stars spend is some portions of the HR diagram. From a purely theoretical point of view, knowledge of the effects of rotation and magnetic fields remains uncertain. As previously mentioned, the treatment of inefficient convection in stars remains a major impediment to our ability to model the interiors of stars.

Bibliography

There are a great many books and review articles on stellar interiors and evolution. One that is somewhat dated, but excellent on the general concepts, is by Schwarzschild (*Structure and Evolution of the Stars*, Princeton University Press, 1958). The book that is the most detailed on the physics of stellar structure and evolution, although virtually unobtainable outside of university libraries and older professional astrophysicists, is by Cox and Giuli (*Principles of Stellar Structure*, Gordon and Breach, 1968).

Stellar Interiors: Thermodynamics

Material properties and stellar models

Thermodynamic quantities of stellar matter are, together with opacity and nuclear reaction rates, the fundamental properties of stellar matter that enter stellar models. These quantities are responsible for the resulting overall parameters of stars and their differentiation according to chemical composition. These *material properties* determine the coefficients of the equations of stellar structure (see STELLAR EVOLUTION). Otherwise, the type of stellar matter would not enter these equations, which express the result of (i) a balance of forces, (ii) a balance between the energy loss at the stellar surface and energy generation in the core, and (iii) stationary energy transport between the core and the surface. Thermodynamics is most directly relevant for the balance of forces, which settles in the *hydrostatic equilibrium*, which is a relation between the local pressure gradient and gravitational acceleration. The force of gravity is determined by the density distribution in the star: thus stellar modeling requires a relation between density and pressure through the specific properties of the matter. More precisely, the relevant properties of stellar matter are expressed by the *equation of state*, connecting pressure p, density ρ, temperature T, and composition. A simple example is the perfect gas law for a fully ionized gas, which may be written as $p = \mathcal{R}\rho T/\mu$; here $\mathcal{R}$ is the gas constant, and μ is the mean molecular weight of the various species contained in the gas. Clearly μ depends on the composition, which is often characterized by the fractional mass abundances X, Y and Z of hydrogen, helium and heavier elements.

However, thermodynamics is also important for other parts of stellar models. In particular, the bulk of most convection zones is essentially adiabatically stratified, that is, the pressure–density–temperature relation is an adiabat. The adiabat is the integrated form of the local adiabatic gradients, which are purely thermodynamic quantities. One of the adiabatic gradients is related to adiabatic sound speed: $c^2 = (\partial p/\partial \rho)_s$ (s being specific entropy). This thermodynamic quantity has another important stellar application, because adiabatic sound speed is the key quantity that determines the frequency of acoustic oscillation modes (for a solar illustration see HELIOSEISMOLOGY: THEORY); however, thermodynamics is also crucial when assessing the importance of non-adiabatic effects (see STELLAR PULSATION). This is understood by realizing that the temperature of the stellar interior is determined by the local energy balance of the outward flux of energy, which begins in the hot stellar core that is driven by nuclear reactions, and ends at the surface when the energy leaves the star in the form of radiation (see STELLAR INTERIORS).

Inside a normal star, the two prevailing modes of energy transport are radiation and convection. Radiative transport is easy to formulate when opacity is high and the limiting diffusion approximation works well. The reciprocal of the opacity is the radiative conductivity which determines the energy throughput in this situation. The opacity results from absorption coefficients, which are obtained from atomic physics, although thermodynamics also enters, because it has to provide ionization equilibrium concentrations and level populations of all the absorbing species.

The problem with radiative energy transport is not so much that the diffusion approximation would be bad (in general, opacities in stellar interiors are high), but rather that a literal application of the equations of radiative transport could result in a temperature gradient so steep that a star becomes convectively unstable: the ensuing convective motion, where hot elements of gas rise, dump their excess heat and then, will in general dominate the energy transport. Following Karl Schwarzschild (see SOLAR INTERIOR), the radiative transport equation is replaced by the one describing convective stratification if the local temperature gradient exceeds the adiabatic temperature gradient. To a good approximation, in the majority of convection zones, the convective stratification is adiabatic. In this case, it is the direct result of a thermodynamic quantity.

However, away from the aforementioned limiting cases, knowledge of thermodynamics is still required. The first case is when convection is not efficient. Then, a significant part of the energy is still being carried by radiation. In this case, material properties (mainly specific heats) are needed to model the real (not just the adiabatic) temperature gradient. The second case is when opacity is not very high (in the layers close to the surface of a star). Then, the diffusion approximation breaks down. Since the mean-free path of radiation becomes large, heat can be instantaneously transported from one part to another. Such non-local effects cannot be treated anymore by differential equations, but by the more complex set of equations of radiation hydrodynamics, for which material properties are again crucial.

Ideal and nonideal plasmas

A useful practical introduction to the equation of state is the book by Eliezer *et al* (1986). On a higher theoretical and systematic level is the book about the physics of Coulomb systems by Kraeft *et al* (1986). The most important classification when dealing with plasmas of stellar interiors is the one in ideal and nonideal plasmas. The simplest model is given by a mixture of nuclei and electrons, assumed fully ionized and obeying the classical perfect gas law. However, this is not the most general model of an *ideal-gas* equation of state: it may include deviations from the perfect gas law, namely ionization or dissociation reactions, radiation and degeneracy of electrons, as long as the underlying microphysics of these additional effects is still ideal, that is, does not contain interactions. The 'particles', however, can be classical or quantum, material or photonic. In such an ideal framework, bound systems (molecules, atoms, ions) are allowed to have internal degrees of freedom (excited states,

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

spin). All such ideal effects can be calculated as exactly as desired.

Nonideal effects in plasmas can be assessed by the so-called coupling parameter Γ. In a plasma of temperature T and density such that particles of charge e have an average distance $\langle r \rangle$ from each other, one can define Γ as the ratio of average potential binding energy over mean kinetic energy $k_B T$ (k_B being the Boltzmann constant)

$$\Gamma = (e^2/\langle r \rangle)/k_B T. \tag{1}$$

For simplicity, this expression is restricted to the case of hydrogen; generalizations to other elements are straightforward. Plasmas with $\Gamma \gg 1$ are *strongly* coupled, those with $\Gamma \ll 1$ *weakly* coupled. A famous example of a strongly coupled plasma is the electron gas in the interior of white dwarfs, where the coupling can become strong enough to force crystallization. Another example is given by the electrons in the conduction band of a metal at room temperature. Weakly coupled plasmas are, for instance, the interiors of stars with masses ranging from the slightly sub-solar ones to the largest.

Basic concepts and dimensional parameters

To describe a degree of 'nonideality' or 'degeneracy' of the plasma, it is convenient to introduce a few dimensionless parameters to express the relative strength of the particular effects, such as the Coulomb interaction or quantum degeneracy. These parameters are defined as combinations of various 'characteristic lengths' resulting from simple physical estimates.

The strength of the Coulomb interaction is given by the density-independent *Landau length* l_L

$$l_L = \frac{e_i e_j}{k_B T}. \tag{2}$$

Although the Coulomb potential has infinite range, the Landau length represents an effective radius of the interaction between particles i and j, i.e. for distances $\gg l_L$ the potential energy is negligible compared to the thermal energy $k_B T$.

The Landau length clearly reflects a degree of nonideality of the plasma and the case of an 'ideal' plasma corresponds to $l_L = 0$.

Another purely classical characteristic length is the *mean distance* between two particles of the same species k ($k = \{e, i\}$)

$$d_k = \left(\frac{3}{4\pi n_k}\right)^{1/3}. \tag{3}$$

Here, n_k is the particle density N_k/V of species k. Note that d_k is the generalization of the quantity $\langle r \rangle$ in equation (1). It does not depend on temperature.

The most evident quantum mechanical characteristic length is the *thermal de Broglie wavelength*

$$\lambda_k = \frac{h}{\sqrt{2\pi m_k k_B T}}. \tag{4}$$

The limits of applicability of various theoretical models of the equation of state are usually described by different dimensionless parameters. The *degeneracy* of species k

$$n_k \lambda_k^3$$

is very closely related to the well known *degeneracy parameter* η (sometimes also denoted ψ) by

$$F_{1/2}(\eta) = \frac{\sqrt{\pi}}{4} \frac{\lambda_e^3 N_e}{V}, \tag{5}$$

where F_i is the Fermi integral

$$F_i(y) = \int_0^\infty x^i [1 + \exp(y + x)]^{-1} \, \mathrm{d}x. \tag{6}$$

In the case of a stellar plasma with heavy nuclei and light electrons, the heavy particles become degenerate only at much higher densities than electrons.

Screening and the Debye–Hückel approximation

All characteristic lengths defined so far demonstrate either purely density- or purely temperature-dependent behavior. No collective behavior of particles has been considered. Here screening is discussed, which for normal stars is the most important deviation from ideality.

The seminal study of collective behavior in a plasma was the Debye–Hückel theory of electrolytical solutions. Despite its phenomenological approach this theory proved to be immensely successful not just for electrolytes, but also for plasma calculations.

Basically, one mixes two ideas. First, assuming nondegenerate electrons, and considering one particular ion being fixed, the mean electron distribution around that ion is given by the *Boltzmann factor*

$$n_e(r) = n_e \exp\left[\frac{+e\phi(r)}{k_B T}\right]. \tag{7}$$

The mean ion density around the same ion is similarly given by

$$n_i(r) = n_i \exp\left[\frac{-e\phi(r)}{k_B T}\right]. \tag{8}$$

Second, one assumes applicability of Poisson's equation for *mean charge distributions* (instead of point charges)

$$\Delta\phi(r) = -4\pi e[n_i(r) - n_e(r)]. \tag{9}$$

The resulting system of equations is complicated and nonlinear; however, if the system is only slightly nonideal, that is, if $e\phi(r)/k_B T < 1$, the linearized system has the well known solution of the static-screened Coulomb potential (SSCP)

$$\phi(r) = \frac{e}{r} \mathrm{e}^{-\kappa r}, \tag{10}$$

where κ is the reciprocal of the *Debye length* r_D

$$r_D = \sqrt{\frac{k_B T}{4\pi(n_e e^2 + n_i e^2)}}. \tag{11}$$

This is the electrostatic and weak-screening approximation to a more general dynamic situation, which plays not only an important role in stellar thermodynamics, but equally in the determination of nuclear reaction rates (see NUCLEAR REACTION RATES).

The chemical picture

With the exception of neutron stars, in stellar interiors the thermal de Broglie wavelength of nuclei, atoms, ions and molecules is always tiny and they can all be treated classically. Only electrons have to be treated according to quantum mechanics. Here, there is a bifurcation into two distinct classes of approach, the 'chemical picture' and the 'physical picture' (see the book by Kraeft *et al* 1986). While in the more conventional chemical picture bound configurations (atoms, ions and molecules) are introduced and treated as new and independent species, only *fundamental* particles (electrons and nuclei) appear in the physical picture. In the chemical picture, reactions between the various species occur, and thus the thermodynamical equilibrium must be sought among the stoichiometrically allowed set of concentration variables by means of a maximum entropy (or minimum free-energy) principle. In contrast, the physical picture has the aesthetic advantage that there is no need for a minimax principle; the question of bound states is dealt with implicitly through the Hamiltonian describing the interaction between the fundamental particles. See the section on the physical picture below.

The free-energy-minimization method

The development of computational methods was strongly stimulated by the requirements for stellar evolution, where data for a wide range of parameters are needed. The chemical picture is very well suited for powerful, approximative models such as the free-energy-minimization method, which became computationally feasible since about 1960. Given a mathematical model for the Helmholtz free energy $F(T, V, \{N_i\})$, where $\{N_i\}$ is a set of particle numbers for all species i present in a plasma, one minimizes F subject to the stoichiometric relations governing possible reactions among the particle species in the plasma. The underlying principle is that nature adjusts the reaction equilibrium such that entropy is maximum (for given energy) or the free energy is minimum (for given temperature).

One starts from the canonical partition function. Consider a physical system (with Hamiltonian H) confined in a box of volume V in contact with a heat reservoir at temperature T. Then the canonical partition function is a trace (denoted by Tr)

$$\mathcal{Z} = \mathrm{Tr}(\mathrm{e}^{-H/k_\mathrm{B}T}). \tag{12}$$

From that, the free energy is obtained by the formula

$$F(T, V, \{N\}) = -k_\mathrm{B}T \ln(\mathcal{Z}). \tag{13}$$

Here, the volume V is implicitly contained in the Hamiltonian operator. The free energy is calculated for all $\{N\}$ which are allowed by the *stoichiometric relations* and a given initial composition. Equilibrium concentrations are those $\{N\}$ that minimize $F(T, V, \{N\})$ for given T, V under the stoichiometric constraints. This gives ionization and dissociation equilibria. Numerically, this will be a task of finding a minimum of a nonlinear function $F(T, V, \{N\})$ in the $\{N\}$-space under the stoichiometric constraints.

The major assumption in any *practical* realization of the free-energy minimization method is that the total partition function $\mathcal{Z} = \mathcal{Z}_\mathrm{total}$ factorizes, that is,

$$\mathcal{Z}_\mathrm{total} = \mathcal{Z}_\mathrm{e}\mathcal{Z}_\mathrm{trans}\mathcal{Z}_\mathrm{conf}\mathcal{Z}_\mathrm{int}, \tag{14}$$

where Z_e here stands for the electronic contribution, $\mathcal{Z}_\mathrm{trans}$ is the result of the integration over momentum space for the heavy particles, $\mathcal{Z}_\mathrm{conf}$ is the configurational integral over configuration space coordinates, and finally $\mathcal{Z}_\mathrm{int}$ is

$$\mathcal{Z}_\mathrm{int} = \Pi\mathcal{Z}_\mathrm{int}^{(i)} \qquad \mathcal{Z}_\mathrm{int}^{(i)} = \sum_{j=1}^{\infty} g_{ij} \exp(-E_{ij}/k_\mathrm{B}T), \tag{15}$$

where E_{ij} and g_{ij} denote energy and degeneracy of the state j of species i, respectively.

When going from the partition function to the free energy, the consequence of the assumed factorizability of the partition function is additivity, or modularity, of the free energy. This modularity accounts for the great appeal of the chemical approach from both a modeling and a computational point of view. Modularity basically tells us that all the interactions can be split into separate parts with clear physical meaning. And if, for example, one part needs to be modified to implement a higher order correction, it can be done without having to worry about consistency with the other parts. Terms can be introduced simply by adding or changing subroutines in a computer program, without a major overhaul of the previous work. That is why sometimes for the sake of modularity even relatively crude approximations are maintained, because a rigorous treatment, in the framework of the exact nonfactorizing partition function, would be entirely prohibitive.

Recovering the Saha equation

By retaining only ideal terms, the free-energy-minimization method falls back to the time-honored *Saha equation*. To illustrate, consider the simplest case, hydrogen ionization ($\mathrm{H} \leftrightarrow \mathrm{H}^+ + \mathrm{e}^-$). A neutral mixture of H-atoms, protons and electrons with particle numbers of N_H, N_p and N_e, respectively, has only one degree of freedom, because of the two relations (N_H^0 being the *total* number of protons, bound and free)

$$N_\mathrm{H} + N_\mathrm{p} = N_\mathrm{H}^0 = \mathrm{const},$$
$$N_\mathrm{e} = N_\mathrm{p}. \tag{16}$$

The degree of freedom is the ionization degree. Its equilibrium value is the one for which the free energy is minimum. The minimum condition is then

$$\frac{N_\mathrm{H}}{N_\mathrm{p}N_\mathrm{e}} = \frac{\lambda_e^3}{V}\mathcal{Z}_\mathrm{int}^\mathrm{H} = \sum_{j=0}^{\infty} g_j \exp\left(-\frac{E_j}{k_\mathrm{B}T}\right), \tag{17}$$

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

(with E_j and g_j denoting the *negative* energy states of hydrogen and their orbital statistical weight, respectively). This is the well known *Saha equation* in astrophysics (known as the law of mass-action in physical chemistry). The infinity of the internal (hydrogenic) partition function is notorious; it has plagued statistical mechanics of plasmas for the last 70 years. The usual argument goes that excited states of hydrogen atoms become infinitely large with increasing quantum number j. Because of this, the infinite partition function would only occur for a single atom in the whole infinite universe. Remedies of the infinity have been involving more-or-less sophisticated truncations of the summation at some level; a judicious choice allows us to model real, interacting plasmas.

Let us note in passing that even the most radical truncation to the ground state of hydrogen (whose orbital statistical weight is one)

$$\frac{N_{\rm H}}{N_{\rm p}N_{\rm e}} = \frac{\lambda_e^3}{V}\exp\left(-\frac{E_0}{k_{\rm B}T}\right) \tag{18}$$

is not devoid of problems because, as one sees easily, it leads to spurious recombinations at high densities and relatively low temperatures. Specifically, in the center of a typical star, the Sun, this equation would predict about 30% neutral hydrogen, which is clearly nonsensical for the prevailing density of 150 g cm^{-3}. The reason for this pathology is that the Saha equation does not contain information about the *size* of the hydrogen atom. Bringing in correction terms that do contain atomic radii amounts to modeling so-called 'pressure ionization'. Only nonideal interaction terms between the species can treat this important physical effect.

Nonideal effects in the chemical picture

Re-deriving the Saha equation with a new method gives no gain though. However, the power of the free-energy-minimization method is precisely that it allows us to include nonideal effects *consistently*. The reason is that any modification to the thermodynamics is only made at one single place (the free energy). Since the ionization degree and all thermodynamic quantities follow from the free energy by purely mathematical steps, all these quantities are consistent with each other. For instance, they automatically obey all Maxwell relations. The corresponding shifts in the ionization equilibria are correct.

Achieving such consistency would be difficult in an approach where one considers the Saha equation and the corresponding thermodynamic quantities separately, all to be modified individually. There would be no general systematic procedure. The free-energy-minimization method, however, achieves it nicely and simply. It is therefore the natural nonideal extension of it to incorporate interactions into simple equations of state which are based on the Saha equation.

As an example, to include screening at the level of the Debye–Hückel approximation, it suffices to add to the total free energy the 'module' for the Debye–Hückel free energy

$$F_{\rm conf} \equiv F^{\rm DH} = -\frac{k_{\rm B}TV}{12\pi r_{\rm D}^3}. \tag{19}$$

Weakly-coupled stellar plasmas

High-mass stars are distinguished by high temperatures, so that even in their center, the kinetic energy $k_{\rm B}T$ of particles largely dominates the electrostatic potential energies. The Sun is somewhat an exception, not so much because it would not qualify as a moderate-mass star, but rather because the helioseismic data put such constraints on the thermodynamic quantities that even very small nonideal deviations are needed in solar models and can therefore be studied in great detail (see SOLAR INTERIOR: EQUATION OF STATE AND OPACITY).

For weakly-coupled plasmas, perturbational approaches are effective. An example is the equation-of-state and opacity effort of the international Opacity Project (OP; see the book by Seaton (1995)). A necessary part of OP is the so-called Mihalas–Hummer–Däppen (MHD) equation of state, which deals with the *heuristic* concept of modified atoms and ions due to the plasma environment. More specifically, the MHD equation of state is based on an occupation probability formalism. The internal partition functions $Z_s^{\rm int}$ of species s adopted by MHD are sums that are made convergent by weights

$$Z_{\rm int}^s = \sum_i w_{is}g_{is}\exp\left(-\frac{E_{is}}{k_{\rm B}T}\right). \tag{20}$$

Here, the index is labels the state i of species s. E_{is} and g_{is} are their energies (in MHD assumed to be unshifted) and statistical weights, respectively, $k_{\rm B}$ is the Boltzmann constant, T is the temperature, and the weights w_{is} are the occupation probabilities that take into account charged and neutral surrounding particles. In physical terms, w_{is} gives the fraction of all particles of species s that can exist in state i with an electron bound to the atom or ion, and $1-w_{is}$ gives the fraction of those that are so heavily perturbed by nearby neighbors that their states are effectively destroyed.

Although the MHD equation of state was originally designed to provide the level populations for opacity calculations of stellar *envelopes*, the associated *thermodynamic quantities* of MHD can none the less be reliably used also for stellar cores. This is due to the fact that in the deeper interior the plasma becomes virtually fully ionized. This rather fortuitous circumstance is the reason why the MHD equation of state fares very well in models of the entire Sun and even in lower-mass models, down to 0.4 $M_\odot$ (for references, see Däppen and Guzik 2000).

A special effect appearing in higher-mass stars is the modification of thermodynamic quantities due to the fact that electrons can become significantly *relativistic*. Inclusion of relativistic electrons is not difficult, however, since it is an ideal-gas effect. It is amazing that the relativistic effect has been detected even in the Sun, despite its tiny amount, because of the superb quality of helioseismological techniques.

Strongly-coupled stellar plasmas

Thermodynamics is more complicated for the interior of low-mass stars, because the kinetic energy of the particles does not dominate the electrostatic potential energies. In the deep interior of these stars, the plasma can become strongly coupled. In addition, temperature alone cannot ionize matter fully, and pressure ionization occurs, which requires more elaborate modeling. The configurational free energy $F_{\rm conf}$ stems directly from the configuration integral $\mathcal{Z}_{\rm conf}$. Besides containing the Coulomb interactions that lead in the classical weakly-coupled approximation to the Debye–Hückel free energy $F_{\rm conf}$, it also contains excluded-volume effects of neutral particles. The well known van der Waals equation of state is based on such an excluded volume effect, but there are more elaborate formalisms of hard-sphere or softer types. Such excluded volume effects become very important in the relatively cold plasmas of low-mass stars or planets (see Saumon *et al* 1995). Note that the sophisticated nature of hard-sphere potentials does not change the basically heuristic nature of the free-energy minimization methods. Only the physical picture can overcome this fundamental limitation (see the following section).

The physical picture

Like the MHD equation of state, the alternative physical-picture activity expansion was also developed as part of an opacity effort, the one pursued by the OPAL group at Lawrence Livermore National Laboratory (Rogers *et al* 1996). The underlying equation of state is based on a sophisticated *systematic* method for including density effects in a plasma. It is clear from the preceding sections that the advantages of the free-energy-minimization method and the chemical picture lie in the possibility to model complicated plasmas, and to obtain numerically smooth and consistent thermodynamical quantities. Nevertheless, the heuristic method of the separation of the atomic-physics problem from that of statistical mechanics is not satisfactory, and attempts have been made to avoid the concept of a perturbed atom in a plasma altogether. This has suggested an alternative description, the physical picture. In such an approach one expects that no assumptions about energy-level shifts or the convergence of internal partition functions have to be made. On the contrary, properties of energy levels and the partition functions should come out from the formalism.

There is an impressive body of literature on the physical picture (Kraeft *et al* 1986; Rogers *et al* 1996; and references therein). However, the majority of work on the physical picture was not dedicated to the problem of obtaining a high-precision equation of state for stellar interiors. Such an attempt was made for the first time by the OPAL group at Livermore as part of their opacity project (see STELLAR OPACITY).

To explain the advantages of this approach for partially ionized plasmas, it is instructive to discuss the activity expansion for gaseous hydrogen. The interactions in this case are all short ranged and pressure is determined from a self-consistent solution of the equations

$$\frac{p}{k_{\rm B}T} = z + z^2 b_2 + z^3 b_3 + \cdots, \tag{21}$$

$$\rho = \frac{z}{k_{\rm B}T}\left(\frac{\partial p}{\partial z}\right), \tag{22}$$

where $z = \lambda_e^{-3}\exp(\mu/k_{\rm B}T)$ is the activity (with λ_e being the thermal de Broglie wavelength of electrons, see above), and μ is the chemical potential. The b_n are cluster coefficients such that b_2 includes all two particle states, b_3 includes all three particle states, etc.

In contrast to the chemical picture, which is plagued by divergent partition functions, the physical picture has the power to avoid them altogether. An important example of such a fictitious divergence is that associated with the atomic partition function. This divergence is fictitious in the sense that the bound-state part of b_2 is divergent but the scattering state part, which is omitted in the Saha approach, has a compensating divergence. Consequently the total b_2 does not contain a divergence of this type. A major advantage of the physical picture is that it incorporates this compensation at the outset. A further advantage is that no assumptions about energy-level shifts have to be made; it follows from the formalism that there are none.

As a result, the Boltzmann sum appearing in the atomic free energy for atoms and compound ions is replaced with the so-called Planck–Larkin partition function (PLPF), given by

$$\mathrm{PLPF} = \sum_{nl}(2l+1)\left[\exp\left(-\frac{E_{nl}}{kT}\right) - 1 + \frac{E_{nl}}{k_{\rm B}T}\right]. \tag{23}$$

The PLPF is convergent without additional cut-off criteria as are required in the chemical picture. However, despite its name the PLPF is not a partition function, but merely an auxiliary term in the second expansion (virial) coefficient of pressure.

Currently available OPAL equation-of-state tables are described in the article by Rogers *et al* (1996). They can be used to model stars down to $0.8M_\odot$. A newer version of OPAL equation-of-state tables is now being released. It will allow the modeling of much less massive stars, down to $0.1M_\odot$. However, models of brown dwarfs and giant planets still need configurational-integral approaches, such as that of Saumon *et al* (1995).

Practical recommendations

When constructing a stellar evolution or pulsation code, opacity and equation of state formulations are necessary. These may be in the form of analytical or in-line routines that calculate the desired opacities or thermodynamic quantities, given as input the temperature, density, and chemical composition. Pre-calculated opacity or equation of state tables may also be used, with appropriate look-up and interpolation routines. Sometimes several

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

tables or analytical fits covering different regions of T, ρ, and composition space must be smoothly joined. The hydrostatic structure calculation may require fewer thermodynamic quantities or derivatives than a pulsation calculation; for example, in pulsation calculations, smooth derivatives of opacity with respect to temperature and density, as well as additional derivatives of thermodynamic quantities, are required.

There are advantages and disadvantages of using tables versus in-line analytical formulations. Tables are often limited in coverage of T, ρ and composition space, and so may not be useful for stellar models over a wide range of masses, compositions, and evolutionary states. Tables do not always include all of the thermodynamic quantities needed for a calculation, and these quantities cannot always be constructed from the information provided. Interpolation within and between tables, or extrapolation off the edges of tables can be difficult and risky, and introduces significant uncertainty into the calculations. The grids of table entries are not always fine enough for good interpolation, or for construction of derivatives using differences between table quantities. On the other hand, tables often include superior physics compared to simple analytical schemes, and can be less computationally expensive than a sophisticated analytical routine.

Analytical procedures can be more flexible, for example in taking into account variations in element mixtures and composition, or in providing smooth derivatives. They also may be modified easily to generate additional thermodynamic quantities. Analytical procedures can also be useful to explore the importance of various physical processes, since these processes can easily be turned on and off, exaggerated with multipliers, etc.

The book by Eliezer *et al* (1986) contains many valuable resources, formulas, and tables for practical calculations of thermodynamic quantities. More rigorous theoretical concepts are discussed in the book by Kraeft *et al* (1986). Finally, references to some commonly used thermodynamic data (and opacity), both analytical and tabular and including information about how to obtain them, are found in the article by Däppen and Guzik (2000). A short version is given elsewhere in this volume (see SOLAR INTERIOR: EQUATION OF STATE AND OPACITY).

Stellar Masses

The mass of a star is arguably its most important property. In this article we will answer four questions concerning stellar masses. How do the properties of stars depend on their masses? What is the smallest and largest mass possible for a star, and why? How do we determine the masses of stars? What distribution of stellar masses occurs when stars form, and why?

Dependence of other stellar parameters on mass

The Russell–Vogt theorem states that, if we know a star's mass and its CHEMICAL COMPOSITION, we can use the laws of physics to determine all of its other properties: its luminosity, its radius, its temperature and density profiles, and how these properties change with time. (We know that this is a slight simplification; for instance, the amount of net ANGULAR MOMENTUM will also affect a star's structure and evolution.) Compared with the possible range of masses a star may have ((0.08–150)$M_\odot$), there is only modest variation possible in the initial composition, and thus it is primarily a star's mass at birth which determines the basic essentials of its structure and future life.

Some of the properties of stars are given in table 1 as a function of stellar mass for stars on the main sequence, the core H-burning phase that accounts for 90% of a star's life. These values have been taken from stellar models computed with a composition that is initially solar. We list the stellar parameters at the beginning and end of the main-sequence lifetimes, except for the lowest-mass stars, for which we adopt the parameters corresponding to an age of 1 Gyr, by which time these stars are stably burning hydrogen.

Generally the behavior of the stellar parameters with stellar mass is quite different for the higher-mass stars ((25–120) $M_\odot$) than for solar-type stars ((0.8–1.2) $M_\odot$). The dependence of luminosity on stellar mass is shown in figure 1. This mass–luminosity relationship is considered one of the most fundamental descriptions of stellar properties; the ability to reproduce this by stellar models was one of the great vindications of theory (see also HERTZSPRUNG–RUSSELL DIAGRAM). EDDINGTON first demonstrated that radiative diffusion in stars requires that the stellar luminosity will depend on mass roughly as the fourth power, i.e. $L \sim M^4$. However, it is clear from figure 1 that no single exponent describes the dependence of luminosity on mass over the entire range of stellar masses. If we consider different mass ranges we would find that the following are good approximations:

$$L \sim M^{1.6} \ (M \approx 100 M_\odot)$$

$$L \sim M^{3.1} \ (M \approx 10 M_\odot)$$

$$L \sim M^{4.7} \ (M \approx 1 M_\odot)$$

and

$$L \sim M^{2.7} \ (M \approx 0.1 M_\odot).$$

The drastic changes seen in the mass–luminosity relation with mass are primarily due to the different opacity sources at work. At the high interior temperatures that characterize high-mass stars, all of the atoms are fully ionized and scattering of x-rays from free electrons dominates the opacity, with no temperature dependence. At lower temperatures, atoms are only partially ionized, and there is a strong temperature dependence in the number of ions. At the very cool temperatures that characterize the lowest-mass stars, molecular hydrogen (H_2) forms, removing the dominant opacity source for solar-type stars, H^- (see also STELLAR OPACITY).

Stellar lifetimes τ_{ms} as a function of mass also show a marked change from solar-type stars to high-mass stars, as evidenced by table 1. For solar-type stars the main-sequence lifetime changes rapidly with mass, while for higher-mass stars the change is far more modest with mass. For most stars, roughly the same fraction of a star's mass (10%) is involved in nuclear burning regardless of mass, and so the relative main-sequence lifetime τ_{ms} will be roughly proportional to the mass (the amount of fuel) and inversely proportional to the luminosity (how quickly the fuel is consumed), i.e. $\tau_{ms} \sim M/L$. Given the mass–luminosity relations above, we can thus estimate the dependence of lifetime on mass as $\tau_{ms} \sim M^{-3.7}$ for solar-type stars, and $\tau_{ms} \sim M^{-0.6}$ for very-high-mass stars. This rule of thumb breaks down for the lowest mass stars, as the stars are fully convective, and the hydrogen-burning main sequence lasts a good deal longer than one would expect. As shown in table 1, a $0.1M_\odot$ star will last 10 trillion years (1.0×10^{13} yr) in a core-H-burning phase, roughly 1000 times as long as the Sun will, rather than the factor of 100 that one would expect, since the entire star provides the nuclear fuel.

During the main sequence the highest-mass stars lose a significant fraction of their mass owing to stellar winds. A star that begins life with $120M_\odot$ will lose $50M_\odot$ (40%) of its mass, while a $60M_\odot$ star will lose $12M_\odot$ (20%), by the end of its main-sequence life. Below $25M_\odot$ the amount of mass lost during main-sequence evolution is negligible, although stellar winds do affect the evolution of even solar-type stars by carrying off angular momentum. Such mass loss is expected to scale with metallicity and thus will be less significant in galaxies of lower metallicity.

Table 1. Properties of main-sequence stars as a function of stellar mass.

Mass ($M_\odot$)	τ_{ms}	Beginning of main sequence				End of main sequence			
		T_{eff} (K)	Spectral type	log $L/L_\odot$	Radius ($R_\odot$)	T_{eff} (K)	Spectral type	log $L/L_\odot$	Radius ($R_\odot$)
120 $M_\odot$	2.56 Myr	53 300	O3 V	+6.25	16	32 900	O9 I	+6.34	48
60 $M_\odot$	3.45 Myr	48 200	O4 V	+5.73	10	12 000	B7 I	+5.99	230
25 $M_\odot$	6.51 Myr	37 900	O8 V	+5.29	6.5	29 000	B0 I	+5.29	18
12 $M_\odot$	16.0 Myr	28 000	B0.2 V	+4.01	4.3	24 400	B0.5 I	+4.46	9.5
5 $M_\odot$	94.5 Myr	17 200	B5 V	+2.74	2.7	15 100	B5 I	+3.15	5.5
2.5 $M_\odot$	585 Myr	10 700	B9 V	+1.60	1.8	9000	A2 III	+1.92	3.8
1.25 $M_\odot$	4.91 Gyr	6380	F5 V	+0.32	1.2	6070	G0 V	+0.66	1.9
1.0 $M_\odot$	9.84 Gyr	5640	G8 V	–0.16	0.9	5790	G2 V	+0.22	1.3
0.8 $M_\odot$	25.0 Gyr	4860	K2 V	–0.61	0.7	5360	K0 V	-0.09	1.1
0.5 $M_\odot$	100 Gyr	3890	M0 V	-1.42	0.4	—	—	—	—
0.2 $M_\odot$	4000 Gyr	3300	M4 V	–2.2:	0.2	—	—	—	—
0.1 $M_\odot$	10 000 Gyr	2900	M7 V	–3.0:	0.1	—	—	—	—

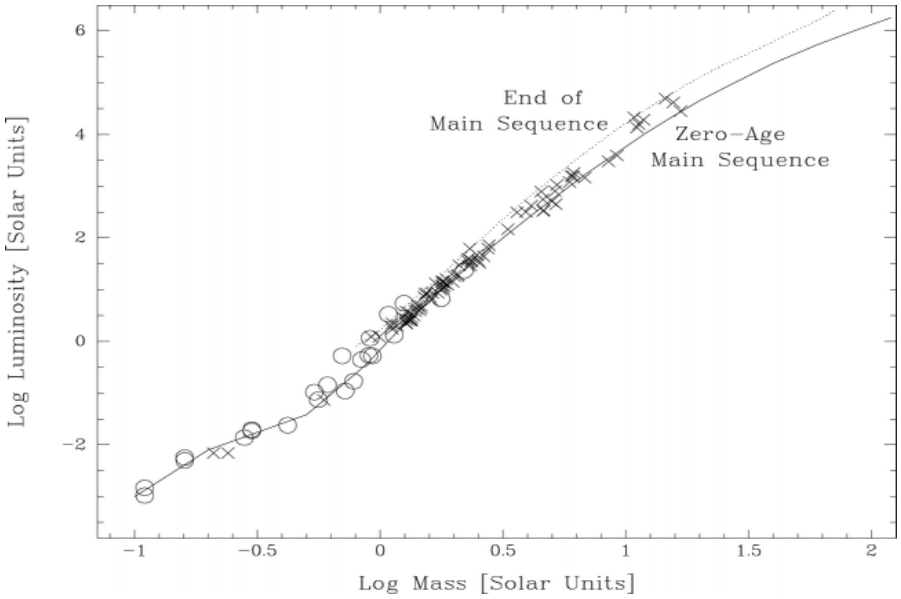

Figure 1. The mass–luminosity relationship as predicted by stellar models is shown by the solid curve for stars with zero age and by the dotted curve for stars at the end of their main-sequence lifetimes, for masses of 0.8 $M_\odot$ (log M = –0.1) and greater. Below that mass, the curve shown is for models with an age of 1 Gyr, as stars of this age have begun to burn hydrogen stably with constant luminosity. (The vast majority of low-mass stars will be at least that old.) The points show the masses and luminosities of 'real' stars for comparison, with the crosses denoting the best determinations from double-lined spectroscopic binaries, and the open circles denoting the best determinations from visual binaries.

It is inappropriate to speak of a spectral type to mass relationship for higher-mass stars: stellar evolution results in a progression from higher effective temperatures to cooler during the core-H-burning lifetime, and during this evolution stars of different masses will pass through a particular spectral type 'stage'. For lower-mass main-sequence stars this is not true, and there is only a slight change of spectral type with evolution (i.e. little change of the effective temperature). For example, a star which is spectroscopically classified as 'O4 V' star may be a zero-age 60$M_\odot$ star, or a slightly older (0.5 Myr) 85$M_\odot$ star, but all stars of spectral type G2 V will have a mass roughly that of the Sun.

Range of stellar masses: the lowest- and highest-mass stars

The masses of stars span the range from 0.08 to 150 (or more) times the mass of the Sun.

At the low-mass end, the 0.08$M_\odot$ limit is set by the stellar core not being hot enough to ignite hydrogen

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

stably. Objects with masses slightly below this limit are called brown dwarfs, and are 'star like' in the sense that nuclear burning of deuterium occurs in their core. Below a mass of $0.015M_{\odot}$ (roughly 16 times the mass of Jupiter) not even deuterium burning can occur, and these objects are perhaps best called planets. Thus there is a natural lower limit to what constitutes a star, although we expect that the mass function (discussed below) should be unaware of this division. We note that the distinction between brown dwarfs and *bona fide* stars is subtle in the following sense: both low-mass stars and brown dwarfs burn primordial deuterium at first, but a 'real' star will 'eventually' settle down to stable H burning; we expect in the case of a $0.08M_{\odot}$ star that this will take approximately a billion years (1 Gyr).

In 2001, a very low mass star (lower than a tenth of a solar mass), located at a distance of only 13 light years, designated as DENIS-P J104814.7-395606.1, was found on the infrared survey DENIS images. On the night of 30 May 2000, the 10 m Keck I telescope was used to obtain a high-resolution spectrogram that showed the presence of a strong cesium absorption line, as well as titanium and vanadium oxide bands. The signature of lithium was not present in the spectrum of the object. The Keck data demonstrated that this object must be a very nearby dwarf (cesium is not detected in giants), with a temperature of about 2200 K and a mass between 90 and 60 Jupiters. The lack of lithium implies that the mass must be larger than 60 Jupiter masses, but does not rule out that it could be a massive brown dwarf. A very nearby dwarf should have an apparent motion with respect to the background of more distant stars. Astronomers at the Observatory of Paris searched for DENIS-P J104814.7-395606.1 in old photographic plates and found it in images obtained during the last 30 years. It has moved considerably between 1986 and 1999. The large proper motion (1.5 arcsec per year) confirms that this is one of our nearest neighbors. The astronomers estimate a distance of about 13 light years. This distance is still uncertain because it is based on comparisons with objects of the same spectral type.

At the other extreme, we do not understand what, if anything, limits how large a mass a star may have. At one time it was thought that radiation pressure acting on grains limited how large a star could form, but we now understand that disks play an important role in the formation of stars. There may be sufficient shielding by the inner part of the disk to mitigate the effects of radiation pressure. It is not clear at this time what role the mergers of protostellar clumps may play in the formation of stars. If the role is appreciable, then there may be *no* natural limit to how massive a star may actually form.

Even if star-formation processes fail to limit the mass of a star, other processes may. Eddington proposed in 1926 that stars more massive than some amount would be pulsationally unstable and should blow off their outer layers, thus limiting their mass. Early estimates of this limit were as low as $60M_{\odot}$. Modern estimates, however, place this limit as high as $440M_{\odot}$, although this is still based on the same classical perturbation linerarization methods used by Eddington. Recent 'nonlinear' analysis (i.e. direct numerical integration of the equations of stellar structure) suggests that the mass loss from such instabilities would only be comparable with the mass loss of radiatively-driven stellar winds in any event.

In this context it is interesting to note that the highest-mass stars we know do all show signs of prodigious mass loss. The highest-mass main-sequence stars known are located in the R136 cluster at the heart of the 30 Doradus nebula in the LARGE MAGELLANIC CLOUD (LMC). These stars have masses which have been conservatively estimated as being as high as $155M_{\odot}$. Spectroscopically the eight most massive of these stars show evidence of extremely high mass-loss rates (mimicking the appearance of WOLF–RAYET STARS), and so one could argue that indeed these stars are not 'stable' in the sense that they are losing a considerable amount of matter.

The luminosities of the most luminous R136 stars are $10^{6.6}L_{\odot}$. Other stars which are of comparable luminosity include HD 5980, a Wolf–Rayet star in the SMALL MAGELLANIC CLOUD (SMC), η CARINAE, a luminous blue variable (LBV) in the Milky Way, Sk − 67º 211, an O3 III star in the LMC, and the Pistol Star, an LBV located near the Galactic center. It is hard to determine masses for LBVs and Wolf–Rayet stars, as these are in an He-burning phase, where the interior models (and hence the mass–luminosity relationship) for massive stars are quite uncertain, but it is clear that these stars evolved from stars of mass similar to that of the highest-mass R136 stars. The mass inferred for the main-sequence star Sk − 67º 211 is also like that of the R136 stars, suggesting that the stars in R136 do not have some kind of special origin. Studies of the youngest OB associations and clusters (i.e. young enough so that not even the highest-mass stars would have evolved) show that the richer the cluster is in stars, the higher the mass of the highest-mass star seen. We now understand that although physics may indeed impose a limit on how massive a star may be, we have not yet encountered this limit in nature.

Determination of stellar masses

How do we determine stellar masses? There are two basic ways: (1) direct determination of masses observationally using binaries and (2) inference of stellar masses using models.

Stellar binaries

Simple Newtonian mechanics, specifically Kepler's third law of planetary motion, allow us to directly determine the masses of stars in some BINARY STAR systems.

'Double-lined' spectroscopic binaries are stars whose spectra show the signature of two stars. The orbital periods of these systems are usually a few days or months, and the line-of-sight (radial) velocities of each component can be directly measured as the DOPPLER EFFECT causes the spectral lines of one star to first appear blueshifted and then redshifted relative to the lines' average position. Masses can be determined directly if the orbital inclination can also be found via light variations (i.e. eclipsing or ellipsoidal) or by the direct resolution of such systems through techniques such as speckle imaging or long-baseline interferometry. The masses and luminosities determined from the best, well-separated binaries are shown in figure 1, and we see that the mass–luminosity relationship inferred from such systems is in excellent agreement with that predicted by modern stellar interior models.

Missing from the figure are any high-mass stars; many of these systems are in physical contact or are sufficiently close to have undergone some mass transfer. Searches for high-mass spectroscopic binaries whose components are cleanly detached are continuing.

For visual binaries, masses can be determined if the period is short enough to be observed and the distance to the system is known. However, the distance needs to be known to high accuracy for the method to yield useful results: a 7% error in the parallax of the system leads to a 20% accuracy in the masses. There are only 14 systems for which good radial-velocity orbits and parallaxes are known, and we include these data in figure 1. New parallax determinations with the HIPPARCOS satellite will provide improved data on many more systems. Since the orbital periods of these visual binaries are tens or even hundreds of years, reliable measurements over a substantial time period are needed for orbit determinations. High-resolution imaging studies with the HUBBLE SPACE TELESCOPE or new ground-based techniques are providing important new fundamental data on such systems.

Stellar models

If the effective temperature and luminosity of a star are known (from spectroscopic observations of a star whose distance is known, either from parallax or from membership in a cluster with a known distance), then stellar interior models can be used to approximate the star's mass. This method is the basis for most of the masses inferred in determining the initial mass function (discussed in the next section).

It is also possible to estimate a star's mass from STELLAR ATMOSPHERE models. Again, spectroscopy is needed of a star with known distance. By fitting the stellar lines and comparison to model atmospheres, it is possible to determine the effective temperature $T_{\rm eff}$ and surface gravity g. Since the star's luminosity L is also known, it is possible to determine the stellar radius R since $L \sim R^2 T_{\rm eff}^4$. The mass of the star can then be found since $g \sim M/R^2$.

For the most massive stars, there appears to be a significant 'mass discrepancy' between the masses derived from stellar atmosphere and stellar interior models, stellar atmospheres predicting masses which are systematically smaller. The reason for this discrepancy is unknown at present, but is largest for the most luminous, massive supergiants, for which there may be factors of 2 differences between the two methods. Attempts to resolve this discrepancy by means of spectroscopic binaries have been frustrated by the same lack of identified high mass 'detached' systems described above.

Distribution of stellar masses

If we were to count stars as a function of mass in the solar neighborhood, we would find that there were far more low-mass stars than high-mass stars. The reasons for this are basically two-fold. Low-mass stars live much longer than do high-mass stars, and so have accumulated over most of the life of the Galaxy, while high-mass stars quickly consume their fuel and die. The second reason, however, is that in a typical star-forming event many more low-mass stars are formed than are high-mass ones.

Knowing the distribution of stellar masses that is obtained when stars form from clouds of gas and dust in space is important for two reasons. First, because the light observed from star clusters and galaxies is dominated by a few of the brightest stars (the tip), it is important to know how many low-mass stars are associated with the iceberg as a whole. Indeed, in a stellar system such as our own Milky Way galaxy, most of the observed luminosity comes from stars greater than $10M_\odot$, while most of the mass is locked up in stars with masses below $1M_\odot$. Secondly, the distribution of stellar masses at birth (the initial mass function (IMF)) provides clues to the processes of stellar formation. Changes in the shape of this distribution function with mass provide evidence for the critical scales associated with the star formation process.

In general the IMF can be thought of simply as a probability function $\phi(M)$, representing the likelihood of forming a star with a mass between M and $M + {\rm d}M$. In 1955 SALPETER found that the IMF of stars near the Sun was well represented as a power law, with $\phi(M) \sim M^{-2.35}$. Modern estimates from studies of OB associations in the Milky Way and LMC suggest that for stars of mass greater than $5M_\odot$ the IMF is indeed very similar to Salpeter's result, with an exponent of -2.3 ± 0.3 obtaining regardless of cluster density or metallicity (figure 2).

For intermediate- and low-mass stars, studies of the IMF have traditionally been done using volume-limited samples of stars found in neighborhood of the Sun. Using a variety of techniques (photometric, spectroscopic and

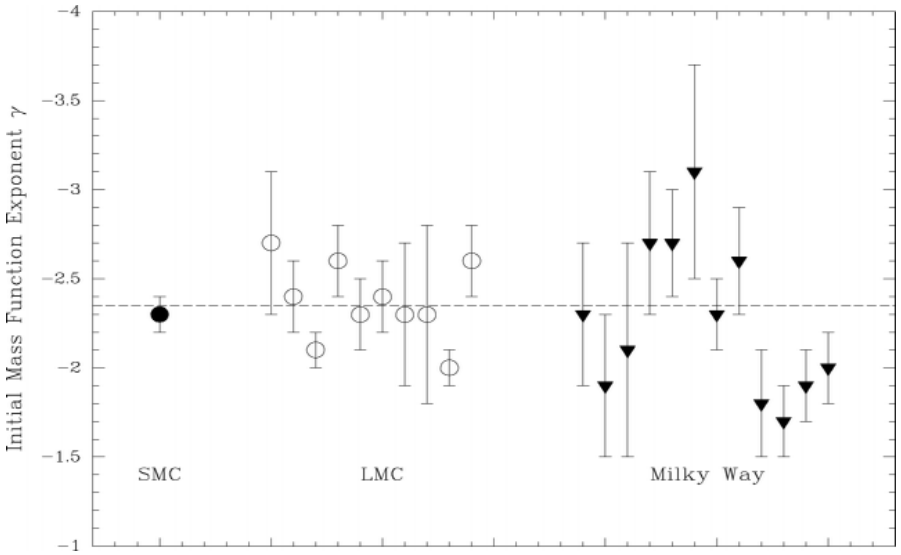

Figure 2. The universality of the IMF for high-mass stars is demonstrated in this figure showing the IMF exponent γ (where the distribution function $\phi(M) \sim M^{\gamma}$) for massive stars in the OB associations of the SMC, LMC and Milky Way. The dashed line is for a Salpeter exponent of −2.35. The metallicities change by a factor of 4 between these three systems.

parallactic) a luminosity function can be constructed for an unbiased sample of stars. Adopting a mass–luminosity relationship appropriate for the sample in question then allows one to transform the luminosity function into a mass function. In practice, one must take into account the metallicity and evolutionary state of the sample, as well as correct for the relative life-times. The derived IMFs will also depend on what assumptions have been made about the star-formation of the region, with increased dependence at lower masses, where the star-formation history over the entire life of the galaxy is relevant. Such studies now suggest that the power law may be somewhat less steep for $(1–5)M_{\odot}$ stars than for stars of higher mass. For stars of even lower mass, studies are hampered by the additional uncertainty of the mass–luminosity relationship for very cool objects. Most work is consistent with $\phi(M) \sim M^{-1.0\pm0.5}$ over the range $(0.1–1)M_{\odot}$. There is disagreement, however, as to whether or not the number of low-mass stars that are formed continues to rise to lower and lower masses, or whether the relationship flattens out or even turns over somewhere near the low-mass end of this range.

Another technique that has been exploited in determining the IMF is the use of star clusters in which all stars appear to have roughly the same age. By using such coeval groups of stars, problems inherent in correcting for star-forming histories are eliminated, although other concerns (such as dynamical evolution) need to be addressed. Studies of GLOBULAR CLUSTERS with ages greater than 1 Gyr derive IMFs consistent with the field down to a limiting masses of $(0.2–0.3)M_{\odot}$. GALACTIC OPEN CLUSTERS with ages 30–500 Myr, perhaps the best place to constrain the IMF near $1M_{\odot}$, confirm that the IMF is less steep than at masses greater than $5M_{\odot}$. Recent studies of nearby young open clusters such as the Pleiades and α Per have begun to probe the IMF down below the hydrogen-burning limit. Finally, by studying clusters still embedded in the molecular cloud cores from which stars form, we can attempt to relate different outcomes of the star-forming process to the initial conditions of formation. Thus far, IMFs derived from a wide variety of stellar populations in the Milky Way and local group galaxies are consistent with having been drawn from the same distribution as stars found in the neighborhood of the Sun. However, these comparisons are still in their infancy: there could be significant, more subtle variations present in the IMF that have gone undetected.

We have not yet touched at all upon the physical causes of the IMF: when an interstellar cloud of dust and gas collapses, what processes dominate and result in the distribution of masses we would observe at some future time? One might naively expect that the dominant physics could be readily deduced from the observed IMF, but this turns out not to be the case, primarily because the IMF appears to be so featureless. Instead, the observed IMF can only be used to constrain star-formation theories at present. Power-law distributions may result from a variety of different scenarios, including so-called ‘fragmentation’ theories. The earliest of these was proposed in 1953 when HOYLE suggested that the Jeans mass (the minimum mass needed for gravitational collapse) could result in a hierarchical distribution of masses. The Jeans mass

depends on both temperature and density, and as a cloud collapses the density will increase, while radiation from newly formed stars controls the gas temperature. However, it is not clear whether this elegant model would apply in a real molecular cloud. Alternatively, the agglomeration of protostellar clumps has been suggested as a way to produce a power law. Yet another theory involves feedback from the formation process itself: ignition of a powerful outflow from the protostar might halt further accretion once a characteristic mass has been reached. The resulting distribution of stellar masses would then depend on the ranges of initial values of a variety of physical parameters. A crucial component in evaluating current theories of star formation is whether or not the IMF is 'scale free' (such would be the case if it were well described by a single power law), or whether there is a characteristic mass scale, as is suggested by current observational evidence that the IMF begins to flatten out around $1M_{\odot}$. Solid observational knowledge of the shape of the IMF at even lower masses, and under differing physical conditions, is a prerequisite to understanding star formation.

Bibliography

The following is a list of interesting papers organized in the same order as the topics discussed in this article. In terms of understanding the physics of stars, and how other stellar parameters depend upon stellar masses, we can do no better than to recommend the following three classics:

Cox J P and Giuli R T 1968 *Principles of Stellar Structure* (New York: Gordon and Breach)

Hansen C J and Kawaler S D 1994 *Stellar Interiors* (New York: Springer)

Schwarzschild M 1958 *Structure and Evolution of the Stars* (New York: Dover)

The realization of these principles can be best seen in actual stellar evolutionary tracks. The dependence of physical parameters on stellar masses used in this article was computed using the evolutionary interior models of Andre Maeder's group in Geneva; these models do an excellent job of matching observations and are well described in the literature. The most recent version of these models can be found in the following two papers:

Schaller G, Schaerer D, Meynet G and Maeder A 1992 New grids of stellar models from 0.8 to 120 solar masses at Z = 0.020 and Z = 0.001 *Astron. Astrophys. Suppl.* **96** 269–331

Schaerer D, Meynet G, Maeder A and Schaller G 1993 Grids of stellar models. II—from 0.8 to 120 solar masses at Z = 0.008 *Astron. Astrophys. Suppl.* **98** 523–7

As for the range of stellar masses, the best discussion for the lowest mass stars can be found in

Burrows A, Hubbard W B, Saumon D and Lunine J I 1993 An expanded set of brown dwarf and very low mass star models *Astrophys. J.* **406** 158–71

For a modern discussion of the importance of the pulsational instability that may exist for the highest mass stars, we recommend the following:

Appenzeller I 1987 Theory of vibrational instabilities in luminous early type stars *Instabilities in Luminous Early Type Stars* ed H J G L M Lamers and C W H Loore (Dordrecht: Reidel) pp 68–72

The exciting discovery of the highest-mass stars may be of interest to some readers:

Massey P and Hunter D A 1998 Star formation in R136: a cluster of O3 stars revealed by Hubble Space Telescope spectroscopy *Astrophys. J.* **493** 180–94

An excellent review of the empirical determination of stellar masses in binary systems is given by

Popper D M 1980 Stellar masses *Ann. Rev. Astron. Astrophys.* **18** 115–64

The first reconsideration of visual binaries based on *Hipparcos* results is given by

Soderhjelm S 1999 Visual binary orbits and masses post Hipparcos *Astron. Astrophys.* **341** 121–40

A discussion of the 'mass discrepancy' for massive stars can be found in:

Burkholder V, Massey P and Morrell N 1997 The 'mass discrepancy' for massive stars: tests of models using spectroscopic binaries *Astrophys. J.* **490** 328–42

As for the distribution of stellar masses, we recommend

Kroupa P, Tout C A and Gilmore G 1993 The distribution of low-mass stars in the Galactic disc *Mon. Not. R. Astron. Soc.* **262** 545–87

Meyer M R, Adams F C, Hillenbrand L A, Carpenter J M and Larson R B 2000 The stellar initial mass function: constraints from young clusters and theoretical perspectives *Protostars and Planets IV* ed V G Mannings, A Boss and S Russel (Tucson, AZ: University of Arizona Press) in press

Scalo J M 1986 The stellar initial mass function *Fundam. Cosm. Phys.* **11** 1–278

and, in particular, a recent conference on the IMF:

Gilmore G and Howell D (ed) 1998 *The Initial Mass Function* (San Francisco, CA: ASP)

Stellar Nomenclature

Stars are identified in various ways. Most bright stars have proper names which are universally recognized—for example, Antares, Rigel, Vega. A more precise designation, applicable to many more stars, including all those of naked-eye magnitude, consists of a letter or number followed by the Latin genitive of the name of the constellation in which the star is situated. This is in fact a combination of two systems, the Bayer letter and the Flamsteed number.

Bayer letters were introduced by the Bavarian lawyer/astronomer Johann Bayer (1572–1625) in his star atlas *Uranometria* of 1603; they consist of a lower-case Greek letter followed by the genitive constellation name; thus the Bayer letter for Antares is 'α Scorpii', for Rigel 'β Orionis' and for Vega 'α Lyrae'. The Bayer letters were allocated approximately in descending order of brightness within the constellation, but this does not hold strictly true in all cases, as Bayer was influenced by the detail of the constellation figure as drawn in his atlas, and also some stars have changed in brightness since Bayer's time. Thus Betelgeuse (α Orionis) is in fact less bright than Rigel (β Orionis). Clearly the number of stars in a constellation allocated Bayer letters is limited to 24, the number of letters in the Greek alphabet.

To overcome this limitation, fainter stars are designated by the numbers allocated to almost 3000 stars by the first Astronomer Royal, John Flamsteed (1646–1719), in his star catalog *Historia Coelestis Britannica*, which was published posthumously in 1725. Flamsteed allocated the numbers in order of increasing right ascension, so the brightest stars do not necessarily have the lowest numbers. Thus the Flamsteed numbers for the three stars mentioned above are 21 Scorpii (Antares), 19 Orionis (Rigel) and 30 Lyrae (Vega), whereas 1 Scorpii, 6 Orionis and 16 Lyrae are very much fainter stars. It is often convenient to abbreviate the constellation name. At its inaugural General Assembly in Rome in 1922 the International Astronomical Union adopted a list of three-letter abbreviations which has remained the standard; thus our three typical bright stars are conveniently designated 'α Sco', 'β Ori' and 'α Lyr'.

The huge numbers of additional faint stars discovered since Flamsteed's time can only be identified by their numbers in various catalogs. These may be designations from 'general' catalogs, such as the *Bonner Durchmusterung* of 1859–62, or *The Bright Star Catalog* (Yale, 1930; fourth revised edition 1982) which uses the same numbers as the *Harvard Revised Photometry* of 1908, therefore known as 'HR' numbers. Some stars have additional designations from catalogs compiled for a specific purpose, for example *The Henry Draper Catalog of Stellar Spectra* (Harvard, 1918–24) or the *General Catalog of Variable Stars* (Moscow, 1958; fourth edition 1985–90). A single star may thus have many designations, depending on the catalogs in which it is listed; hence Vega also has the numbers HR 7001 (from *The Bright Star Catalog*), BD + 38°3238 (from the *Bonner Durchmusterung*) and HD 172167 (from *The Henry Draper Catalog*).

Stellar Opacity

The monochromatic opacity, κ_ν, quantifies the property of a material to remove energy of frequency ν from a radiation field. A harmonic average of κ_ν, known as the Rosseland mean, κ_R, is frequently used to simplify the calculation of energy transport in stars. The term 'opacity' is commonly understood to refer to κ_R.

Opacity plays an important role in stellar modeling because for most stars RADIATION is the primary mechanism for transporting energy from the nuclear burning region in the core to the surface. Depending on the mass, convection and electron thermal conduction can also be important modes of stellar energy transport. The efficiency of energy transport is related to the temperature gradient, which is directly proportional to the mean radiative opacity in radiation-dominated regions. When the radiative opacity is large, convection can become the more efficient energy transport mechanism. Electron conductive opacity, the resistance of matter to thermal conduction, is inversely proportional to electron thermal conductivity. Thermal conduction becomes the dominant mode of energy transport at high density and low temperature.

The removal of energy from a beam of photons as it passes through matter is governed by spectral line absorption (bound–bound), photoelectric absorption (bound–free), inverse bremsstrahlung (free–free) and photon scattering. Stimulated emission acts as negative opacity by creating photons that add to the beam. Photon scattering is not true photoabsorption; it acts to reduce the photon flux by redirecting photons out of the beam and is not subject to stimulated emission.

The first step in computing the opacity is the determination of the equation of state, followed by the calculation of the various absorption and scattering cross-sections and finally the integration over frequency to obtain κ_R. Therefore, opacity calculations bring together several distinct disciplines, such as equation of state, atomic physics, spectral line broadening, as well as plasma collective behavior. These provide ion abundances, energy level values, radiation transition probabilities, spectral line profiles and structure factors needed to carry out the calculations. Since atoms from different elements absorb energy of a given frequency at different rates, it is necessary to also know stellar elemental abundances.

Molecules can form in the atmospheres of cool stars (see STELLAR ATMOSPHERES: COOL STARS). The discussion herein is concerned with stellar interior opacities and does not encompass the molecular regime. The methods for calculating molecular opacities follow a somewhat similar path.

History of opacity calculations

As long ago as 1926 Eddington identified opacity as one of two clouds obscuring stellar model calculations, the source of stellar energy being the other. At that time it was thought that bound–bound absorption was not a significant source of opacity. It was 40 yr later that Cox and Stewart included spectral lines in opacity calculations. This led to opacity increases exceeding a factor of 3 at some temperature–density conditions. These enhanced opacities greatly improved the quality of stellar models. Even so, several properties of stars known to be sensitive to opacity resisted explanation. It was another 20 yr before Simon speculated that the most likely explanation was that the heavy element contribution to opacity was still significantly underestimated. Two independent efforts, OPAL and OP, recalculated stellar opacities and found that an improved treatment of atomic data leads to an additional factor of 3 increase in the opacity under some conditions. The OPAL work was carried out by Iglesias, Rogers and Wilson. The OP work was carried out by Seaton and a international group of collaborators. These new opacities helped resolve a number of long-standing problems in stellar modeling, particularly in regard to pulsating stars. Direct laboratory verification of the new opacity calculations has only recently started to appear. These show good agreement with the most recent calculations and large differences with standard opacity results used prior to 1985.

Definition of κ_ν

The total extinction from a beam of photons as it passes through matter is given by

$$\kappa_\nu = \kappa_\nu^{\mathrm{abs}} + \kappa^{\mathrm{S}}$$

where

$$\kappa_\nu^{\mathrm{abs}} = (1 - \mathrm{e}^{-h\nu/kT}) \sum_j x_j (\kappa_j^{\mathrm{bb}} + \kappa_j^{\mathrm{bf}} + \kappa_j^{\mathrm{ff}})$$

is the total photoabsorption, the sum j is over all elements in the mixture, x_j is the elemental number fraction, κ_ν^{bb}, κ_j^{bf} and κ_j^{ff}, are, respectively, the bound–bound, bound–free and free–free frequency-dependent photoabsorption contributions to opacity, κ^{s} is the scattering contribution and the factor $1 - \exp(-h\nu/kT)$ accounts for stimulated emission. When the density is low enough that the material can be considered to be composed of individual particles, the photon extinction due to a process p is given by

$$\kappa_\nu^{\mathrm{p}} = \sum_j N_j \sigma_\nu^{\mathrm{p}j}$$

where N_j is the number density of particles of type j and $\sigma_\nu^{\mathrm{p}j}$ is the cross-section for photons of frequency ν. Opacity has units of inverse length. However, numerical values are generally expressed as κ_ν/ρ in units of $\mathrm{cm}^2\ \mathrm{g}^{-1}$.

Mean opacities

The radiation transfer equation describes the transport of energy by photons and is equivalent to the Boltzmann equation in the kinetic theory of particle transport. For steady-state conditions it is given by

$$\frac{\mathrm{d}I_\nu(s, \boldsymbol{n})}{\mathrm{d}s} = -\kappa_\nu I_\nu(s, \boldsymbol{n}) + j_\nu \qquad (1)$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

where $I_\nu(s, \boldsymbol{n})$ is the radiation intensity at frequency ν in the direction $\boldsymbol{n}$ as a function of distance s, and j_ν is the emissivity.

STELLAR INTERIORS are 'collision dominated' so that the material can be considered to be in thermodynamic equilibrium at the local value of temperature and density. Also, because of the small temperature gradient, the radiation intensity is very close to Planckian, i.e. in a state of local thermodynamic equilibrium. Consequently, Kirchhoff's law,

$$j_\nu = \kappa_\nu B_\nu(T)$$

applies, where

$$B_\nu(T) = (2h\nu^3/c^2)(\mathrm{e}^{h\nu/\kappa T} - 1)^{-1}$$

is the Planck function. In addition, conditions change slowly over many photon mean-free paths and the radiation flow is nearly isotropic, so that the radiation transfer equation greatly simplifies. In this limit, known as the diffusion approximation, the solution to equation (1) as a function of radius, for a non-dispersive medium, integrated over frequency is

$$F(r) = -\frac{4\pi}{3}\frac{1}{\kappa_\mathrm{R}}\frac{\mathrm{d}B(r,T)}{\mathrm{d}r} \tag{2}$$

where $F(r)$ is the total flux, $B(r, T)$ is the integral of B_ν over frequency and

$$\frac{1}{\kappa_\mathrm{R}} = \int_0^\infty \mathrm{d}\nu \frac{1}{\kappa_\nu}\frac{\mathrm{d}B_\nu}{\mathrm{d}T} \Bigg/ \int_0^\infty \mathrm{d}\nu \frac{\mathrm{d}B_\nu}{\mathrm{d}T} \tag{3}$$

defines the Rosseland mean opacity. Equation (2) recovers the correct asymptotic solution to the transfer equation and the correct flux transport. The harmonic average in equation (3) emphasizes regions of weak absorption, where most of the energy flux is transported. A large value of the opacity indicates strong absorption from a beam of photons, whereas a small value indicates that the beam loses very little energy as it passes through the medium.

Near the surface of a star conditions change very rapidly and the material becomes optically thin. In this limit the assumptions leading to the diffusion approximation break down and a straight arithmetic average of $\kappa_\nu^{\mathrm{abs}}$, known as the Planck mean opacity,

$$\kappa_\mathrm{P} = \int_0^\infty \mathrm{d}\nu\, \kappa_\nu^{\mathrm{abs}} B_\nu(T) \Bigg/ \int_0^\infty \mathrm{d}\nu B_\nu(T)$$

is more suitable. In contrast to κ_R, strong absorption regions provide the major contributions to the Planck mean opacity. Note also that scattering is not included in the Planck mean.

The mean opacities greatly simplify solutions of the radiation transfer equation, but there are circumstances where it is necessary to use κ_ν directly. An example is radiatively driven diffusion in which low-abundance species are pushed toward the surface by a net radiation force in the field of the dominant species. This is thought to be the mechanism that causes large overabundances of Mn and Hg in the atmospheres of some late B and A stars.

Equation of state

Equation of state plays an important role in opacity calculations by providing the initial state occupation numbers needed to obtain κ_ν and also by determining the set of final states that exist at particular plasma conditions. This is a statistical mechanics problem that is complicated by the long-ranged Coulomb interaction between the particles. Two types of approaches are used to calculate the equation of state. One is the 'chemical picture' method which is based partly on intuitive reasoning, since it postulates the effect of the PLASMA on bound states to avoid the divergence of the atomic partition function. Numerous procedures have been proposed, but only one of these receives much current use. It is based on occupation probabilities, w, that separate the statistical weight for a particular state into a part that acts as a localized few-body (bound) state and a part $1 - w$ that acts as a delocalized (continuum) state. In this approach the bound state energies remain those of an isolated particle, but bound states are effectively destroyed by the action of the surrounding electric microfields when $w \to 0$. This results in a convergent bound state partition function.

The other approach used to calculate the equation of state is known as the 'physical picture' because the starting point is the Coulomb interaction between electrons and nuclei. It is based on an activity expansion of the grand canonical partition function for a plasma. This approach gives directly from theory the plasma effect on bound states and convergent atomic partition functions.

Photoabsorption and scattering processes

The physical extent of the absorbing atoms and ions in the plasma is generally much less than the wavelength of the radiation, so that only single-photon absorption through the electric-dipole interaction is of practical importance in opacity calculations. Electric-quadrupole absorption and magnetic-dipole absorption are smaller by several orders of magnitude in the same spectral region. Absorption of two or more photons at a time is also much less likely than single-photon absorption and has been shown to be an insignificant source of opacity in stellar plasmas. However, two-photon processes are involved in the scattering of radiation. During a scattering event an electron absorbs a photon of frequency ν and immediately re-emits another photon of frequency ν' in an arbitrary direction, effectively removing energy from the beam.

Bound–bound absorption

$$\mathrm{P_i} + h\nu \to \mathrm{P_f}.$$

Bound–bound transitions in atoms and ions are possible when the photon frequency is close to $h\nu_{\mathrm{if}} = E_\mathrm{f} - E_\mathrm{i}$, where E_i and E_f are the initial and final state energies. The cross-section for this process is given by

$$\sigma_{\mathrm{if}}(\nu) = \frac{2\pi^2 e^2}{mc} f \phi_{\mathrm{if}}(\nu),$$

where

$$f = \frac{8\pi^2 m \nu_{\rm if}}{3 g_{\rm i} e^2 h} \left| \int_0^\infty \Psi_{\rm f}^*(\boldsymbol{r}) \boldsymbol{D} \Psi_{\rm i}(\boldsymbol{r})\, {\rm d}\boldsymbol{r} \right|^2$$

is the oscillator strength for the i → f transition,

$$\boldsymbol{D} = e \sum_n \boldsymbol{r}_n$$

is the dipole moment summed over all the electrons in P_i, m is the electron mass, g_i is the statistical weight, and Ψ_i^* and Ψ_f are the initial and final state wavefunctions. The total bound–bound cross-section is obtained by summing over all initial and final bound states in the plasma.

The line shape function, $\phi_{\rm if}(\nu)$, includes several processes. Natural broadening is a consequence of the finite lifetime of excited states in the radiation field. It has a normalized Lorentzian profile,

$$\phi(\nu) = 2\pi\Gamma[(\nu - \nu_{\rm if})^2 + (\pi\Gamma)^2]^{-1}$$

where Γ is the damping constant. The wings of the Lorentzian fall off as $\Delta\nu^2 = (\nu - \nu_{\rm if})^{-2}$, so that the infrared wing of the line can be an important source of opacity at very low density. However, the low-frequency line profile far from line center is expected to fall off as $\Delta\nu^4$ similarly to Rayleigh scattering and *ad hoc* methods are sometimes introduced to force this behavior. The thermal velocity distribution of the radiating atoms gives rise to a statistical Doppler shift of radiation frequencies that has a Gaussian distribution whose wings fall off rapidly compared with $\Delta\nu^2$.

As the density increases, other particles in the vicinity of the radiator increasingly affect the line shape. Electrons and ions are the primary perturbers when the ionization degree exceeds a few per cent, but neutrals can be important at low temperature. There is a large literature associated with the theory of one- and two-electron atoms and ions and accurate line shapes are available for these radiators. For hydrogenic ions, where there is degeneracy for levels with the same principal quantum number, the major source of line broadening is due to the linear Stark shift produced by the electric microfield of neighboring ions. In the simplest calculations the ions are assumed to be quasi-static and randomly distributed, leading to the Holtzmark microfield. At high density Coulomb interactions affect the microfield distribution. For practical calculations, electronic collisions with the radiator can be viewed as random fast events compared with the lifetime of the radiator and, since the energy transfers are small, the line shape can be treated by perturbation theory. For helium-like ions the principal quantum number degeneracy is removed for deeply bound states, so that ion perturbations occur through the quadratic Stark effect. Electronic contributions are more important in this situation.

The theory of multielectron atoms and ions is much less complete, and simple methods are generally used to approximate $\phi_{\rm if}$. For radiators with more than two bound electrons, electrons are the major contributor to pressure broadening and the contribution of ions is generally ignored in opacity calculations. The effect of the much faster-moving electrons is usually treated in the impact approximation which assumes that only one electron at a time collides with the radiator, instantaneously cutting off its wave train. This approximation also gives a Lorentzian line shape. Assuming that the different broadening effects are independent, it is possible to convolve the Lorentzian for natural broadening with the Lorentzian for impact broadening to obtain a new Lorentzian whose half-width at half-maximum (HWHM) is just the sum of the HWHMs for natural and pressure broadening. Convolution of this Lorentzian with a Gaussian to account for Doppler broadening then gives a composite shape known as a Voigt profile. Recent line width measurements of $\Delta n = 0$ transitions in boron and carbon ions indicate that the Voigt profiles may provide only a rough approximation. Fortunately, stellar opacity is not very sensitive to moderate changes in line shapes, but this is a source of uncertainty in the calculations.

Bound–free absorption

$$P_i + h\nu \rightarrow P_f^+ + e.$$

Bound–free transitions are possible when $h\nu$ is greater than the ionization potential, I, of a bound electron. The cross-section for this process is

$$\sigma_{\rm i}^{\rm bf}(\nu) = \frac{4\pi^2}{3 g_{\rm i} c}(I + \varepsilon) \left| \int \Psi_\varepsilon^*(\boldsymbol{r}) \boldsymbol{D} \Psi_{\rm i}(\boldsymbol{r})\, {\rm d}\boldsymbol{r} \right|^2 \qquad (4)$$

where the ejected electron has the energy $\varepsilon = h\nu - I$, and $\Psi_\varepsilon(\boldsymbol{r})$ is the scattering wavefunction of the ejected electron. The total cross-section for a given frequency interval is obtained by summing over all initial and final states. Equation (4) assumes that the photoionization edge is sharp. However, because of the merging of high-lying lines just below the continuum, the edge is broadened. Simple procedures, that redistribute the oscillator strength in the vicinity of the edge, are generally introduced to approximate this type of broadening.

For complex ions, bound states can overlap in energy with the continuum. If the Hamitonian connects a bound and a continuum state, the eigenfunction is mixed, introducing resonances into the bound–free continuum, as was first recognized by Fano. This has not been found to have a significant effect on stellar opacity and the autoionizing lines are frequently treated as ordinary broadened lines.

Free–free (inverse Bremsstrahlung) absorption

$$P + e_i + h\nu \rightarrow P + e_f.$$

For free–free electronic transitions the initial state density is also continuous and its distribution is given by Fermi statistics. Dipole-allowed transitions can only occur in the presence of ions, otherwise energy and momentum cannot be simultaneously conserved. The free–free cross-section

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

can be calculated from the dipole acceleration formulation in the form

$$\sigma^{\mathrm{ff}}(\nu) = \frac{e^4}{3\pi\nu^3 m^2 c} \sum_{l_\mathrm{i}} \sum_{l_\mathrm{f}} \max(l_\mathrm{i}, l_\mathrm{f})\, \delta(l_\mathrm{i} - l_\mathrm{f} \pm 1) \times \left| \frac{\mathrm{d}V}{\mathrm{d}r} \right|^2_{\mathrm{if}} p(\varepsilon_\mathrm{i})[1 - p(\varepsilon_\mathrm{f})] \quad (5)$$

where l_i and l_f are the angular momenta of the initial and final states, $|\mathrm{d}V/\mathrm{d}r|_{\mathrm{if}}$ is the matrix element of the radial derivative of the atomic potential for continuum states i and f, $p(\varepsilon_\mathrm{i})$ is the occupation probability of the initial state, and $1 - p(\varepsilon_\mathrm{f})$ is the availability of the final state. Relativistic corrections to σ^{ff} can be significant when $\varepsilon_\mathrm{f} > 10$ keV. Relativity increases the solar center opacity by about 0.2%. The inverse bremsstrahlung cross-section is often normalized to the classical Kramers cross-section. This ratio is known as the free–free Gaunt factor. Inverse electron–electron quadrupole bremsstrahlung can also contribute to the opacity at high temperature and low density.

Photon scattering

$$\mathrm{e_i} + h\nu \rightarrow \mathrm{e_f} + h\nu' \qquad \text{free electron}$$

$$\mathrm{P} + h\nu \rightarrow \mathrm{P} + h\nu' \qquad \text{bound electron (low energy).}$$

Photons scatter mainly off of the plasma electrons, primarily free electrons at high temperature and bound electrons at low temperature. Scattering from nuclei is much less important. For most stellar applications photon scattering can be considered to be coherent ($\nu = \nu'$), but non-coherent scattering ($\nu \neq \nu'$) in which the incoming and outgoing photon have different ν can also occur through high-energy Compton scattering from free electrons or by Raman scattering in the molecular regime.

The classical picture for scattering of a photon from a bound electron demonstrates the connection between the two most important scattering mechanisms; Rayleigh and Thomson scattering. The classical scattering cross-section ($h\nu < 0.511$ MeV) has the form

$$\sigma_\mathrm{S}(\nu) = \sigma_\mathrm{T} \frac{\nu^4}{\nu^2 - \nu_{\mathrm{if}}^2 + (\nu_{\mathrm{ij}}\gamma)^2} \quad (6)$$

where

$$\gamma = e^2 \nu_{\mathrm{if}}^2 / 2\pi^2 m c^3 \quad (7)$$

and

$$\sigma_\mathrm{T} = \frac{8\pi}{3} \left(\frac{e^2}{m_\mathrm{e} c^2} \right)^2 \quad (8)$$

is the Thomson cross-section. Rayleigh scattering occurs when $\nu \ll \nu_{\mathrm{if}}$, so that $\sigma_\mathrm{S} \propto \nu^4$. In the other extreme ($\nu \gg \nu_{\mathrm{if}}$), where the energy of the incoming photon is so high that the scattering electron acts nearly as a free particle, σ_S approaches the Thomson free electron cross-section. Thomson scattering is low-energy Compton scattering. When the energy of the scattered photon is in the keV range, as occurs in high-temperature stellar matter, relativistic effects modify the Compton cross-section and pair production can occur. Sampson expressed these corrections for the total scattering cross-section in the form of the multiplicative factor $(n_{\mathrm{ee^+}}/n_\mathrm{e})G(u, T')$, where $n_{\mathrm{ee^+}}$ is the total number of electrons and positrons, n_e is the number of electrons, $u = h\nu/kT$ and $T' = kT/mc^2$. Additional corrections are required if the electrons are degenerate.

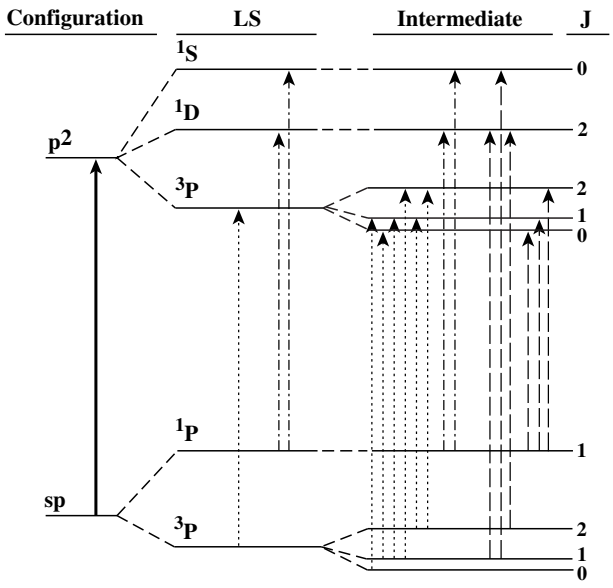

Figure 1. Schematic diagram of possible absorptive transitions between the sp and p^2 configurations in various approximations. Configurational (DCA) transition (solid arrow); singlet transition (short-dashed arrow); triplet transition (short-long-dashed arrow); intercombination transition (long-dashed arrow). J is the total angular momentum of the state.

Atomic data

Several possible levels of detail in the atomic data needed to calculate the energy levels and oscillator strengths are illustrated in figure 1. The example is for transitions that connect two electrons in an sp configuration to a p^2 configuration through a one-electron jump. In the simplest case all transitions are assumed to have the same energy. Opacity calculations that carry out a sum over a large number of configurations in this approximation are referred to as detailed configuration accounting (DCA) methods. This was the method used in the earliest bound–bound calculations. However, the DCA approach neglects non-spherical interactions that remove the degeneracy and lead to configuration term structure. In light elements the dominant non-spherical term is the Coulomb interaction between the electrons, which leads to pure LS coupling. In LS coupling the single spectral line of the DCA method in figure 1 is split into three distinct lines corresponding to a triplet and two singlet terms. With heavier elements, such as those in the iron group, the interaction between the electron spin and the magnetic field resulting from

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the electron orbital motion is no longer negligible and requires coupling of the LS angular momentum states, known as intermediate coupling. In intermediate coupling the three lines of the LS coupling scheme split into eight lines having no net total spin change, $\Delta S = 0$, and six intercombination lines having $\Delta S = \pm 1$. For more complicated configurations the increase in the number of spectral lines is more dramatic. For heavy elements this results in an enormous array of spectral lines that can be treated by statistical methods when the density is high enough that these features merge into a quasi-continuum.

The most accurate atomic data are obtained from relativistic self-consistent field methods such as multiconfiguration Dirac–Fock, but this is very computer intensive when data for millions of transitions are required. The most extensive multiconfiguration atomic data tables have been produced by the Opacity Project using the close-coupling method. These calculations are mostly non-relativistic.

Fortunately, the important thing for opacity calculations is the distribution of oscillator strength. The exact location of lines is only of secondary importance. Consequently single-configuration calculations are usually used. Parameterized potentials have proven to work well for generating the vast amount of data required with accuracy similar to single-configuration Hartree–Fock.

The effect of elemental composition on stellar properties

Stars are composed mainly of hydrogen and helium whose frequency-dependent absorption spectrum is characterized by strong lines separated by regions of weak absorption. Because low-abundance heavy ions have a more complex absorption spectrum, they contribute disproportionately to κ_R by filling in regions of low absorption in the H–He spectrum.

The total mass of all elements heavier than helium generally constitutes less than 2% of the mass of a star (see STELLAR MASSES). This percentage is known as its 'metallicity'. Even so, low-abundance elements such as nickel can significantly affect the opacity when the temperature is in the range where the M shell is partially filled. Because type I stars like the Sun are not old enough that significant burning of elements heavier than helium has occurred, it is normally assumed that these abundances pertain throughout the entire star. Consequently, for most purposes, it is possible to characterize stellar mixtures with just the three variables X, Y and Z, where X is the hydrogen mass fraction, Y is the helium mass fraction and Z is the heavy element mass fraction, i.e. the metallicity. Within this constraint Z can vary, but the abundances of heavy elements relative to each other are fixed. Even without nuclear burning, however, these relative values can vary throughout the star owing to diffusion.

Figure 2 compares the monochromatic opacity for a hydrogen–helium mixture with a typical type I stellar composition having $Z = 0.02$. The assumed temperature–density conditions are found in the pulsational driving region of Cepheid variables. The small heavy element admixture dramatically increases the absorption for $u > 3$, corresponding to photon energies above 80 eV; this results primarily from transitions originating in the M shells of multiply ionized ions of iron. As a result, even though hydrogen and helium are the most abundant species they are not the main contributors to the opacity at these plasma conditions. They do, nevertheless, play an important role by contributing most of the free electrons that determine the rate of recombination of the heavier elements. These electrons also contribute to electron scattering and free–free absorption.

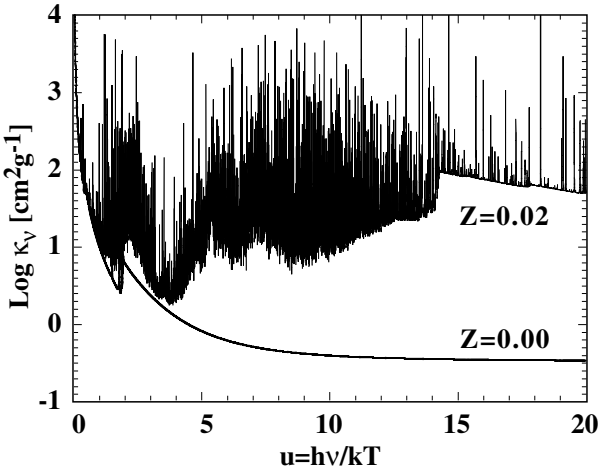

Figure 2. Log κ_ν versus $u = h\nu/kT$ for $T = 316\,000$ K and $\rho = 1 \times 10^{-5}$ g cm^{-3}. Results are shown for $Z = 0$ and $Z = 0.02$ with $X = 0.7$ and $Y = 1 - X - Z$. The heavy element calculations were carried out in intermediate coupling.

Figure 3 compares the opacity versus temperature for the Sun and a Cepheid variable with a mass 6.5 times solar. Because of their mass difference and location on the HERTZSPRUNG–RUSSELL DIAGRAM these stars follow very different temperature–density tracks. The opacity of the solar plasma when heavy elements are left out of the mixture is also shown. Again heavy elements dominate the opacity throughout most of the stellar interior. For stars of one solar mass or greater core temperatures can exceed 10 million kelvins, so that the plasma is highly ionized and even heavy elements such as iron may have only a few bound electrons. In this situation the main contributors to opacity are bound–free absorption in heavy elements, free–free absorption from protons and He nuclei and photon scattering from free electrons. For example, at the solar center the opacity is 40% bound–free, 30% free–free and 30% scattering. In contrast, near the solar surface the degree of ionization is very low and, since the strongest bound–bound transition energies are large compared with kT, atoms make a very small contribution to opacity. In this case the opacity of H^-, which has a

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

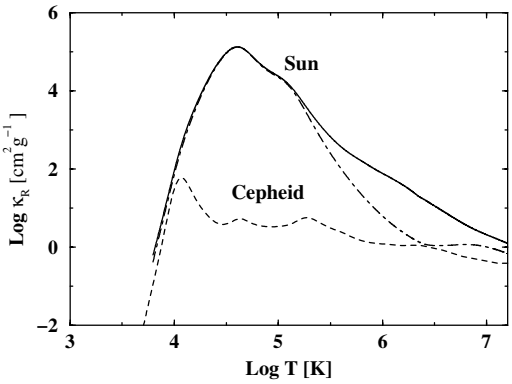

Figure 3. Log κ_R versus log$T$ for the Sun (solid) and a Cepheid variable (dashed). The assumed heavy element content is $Z = 0.02$. For these stellar tracks, X is around 0.7 for $T < 4 \times 10^6$ K, but is less at higher temperature due to nuclear burning. The upper temperature limit (1.56×10^7 K) corresponds to the solar center. Cepheid core temperatures are about an order of magnitude greater. Also shown is the opacity for the temperature–density conditions along the solar track assuming $Z = 0$ (dot-dashed).

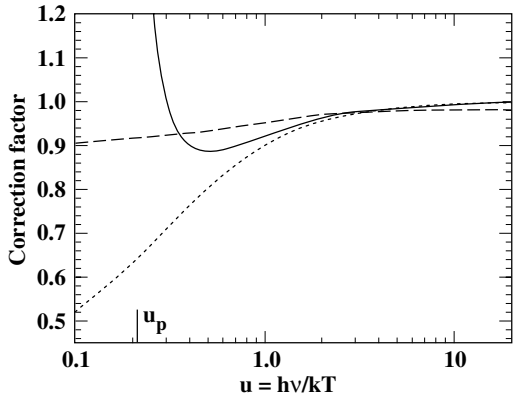

Figure 4. Plasma dispersion, screening plus ion correlational, and degeneracy corrections to inverse bremsstrahlung expressed as ratios $g_{\rm eff}(\nu)/g_0(\nu)$, where $g_{\rm eff}$ is the Gaunt factor including one of these effects and g_0 is the Gaunt factor without these effects included. Plasma dispersion (solid); screening plus ion correlations (short-dashed); degeneracy (long-dashed). The location of the plasma frequency is indicated by $u_{\rm p}$.

binding energy of only 0.74 eV, is a major contributor to opacity, even though its abundance is generally less than 10^{-7}. Rayleigh scattering from H and He is also important near the surface where all atoms are nearly neutral. In the intermediate regions, the opacity is relatively featureless. The maximum near $T = 40\,000$ K is in the middle of the H–He ionization zone and is due mainly to bound–bound absorption.

The Cepheid opacity function in figure 3 is more complex than the corresponding solar opacity function, displaying two additional local maxima. For the Cepheid the H–He maximum separates into a maximum near $T = 10\,000$ K due to H ionization and a maximum near $T = 40\,000$ K due to H–He ionization. The third maximum, near $T = 200\,000$ K, is due mainly to bound–bound transitions occurring in M shell iron. For this reason it is known as the 'Z bump'. The presence of the local maximum near $T = 40\,000$ K is what drives the pulsational instability observed for Cepheids, while the Z bump plays a secondary role by affecting the period ratios between the fundamental mode and its overtones. The solar opacity is much higher at a given temperature because, owing to the higher density, the bound states contributing to the bound–bound and bound–free opacity are more highly occupied.

Plasma environmental effects

The opacity cross-sections discussed above assume that photon extinction processes occur in isolation and ignore the effects due to the surroundings. As the density increases these effects can modify the cross-sections but are generally small for stellar plasmas. However, for some situations, such as the center of the Sun, relatively small changes in the opacity affect quantities such as the neutrino generation rate through small changes in the estimated temperature (see also SOLAR INTERIOR: EQUATION OF STATE AND OPACITY). Consequently, there has been theoretical interest in the effect of collective phenomena on opacity. Collective effects due to plasma density oscillations become important when the plasma frequency,

$$\nu_{\rm p} = \frac{N_{\rm e} e^2}{\pi m_{\rm e}}$$

is comparable with the mean photon frequency.

Dispersion

In dispersive media the Planck function in equation (3) is modified by the factor n_ν^2 so that the Rosseland mean opacity is given by

$$\frac{1}{\kappa_{\rm R}} = \int_{\nu_{\rm p}}^{\infty} {\rm d}\nu \frac{n_\nu^2}{\kappa_\nu} \frac{{\rm d}B_\nu}{{\rm d}T} \Bigg/ \int_0^{\infty} {\rm d}\nu \frac{{\rm d}B_\nu}{{\rm d}T} \qquad (9)$$

where n_ν is the refractive index, which has the approximate form ($\nu > \nu_{\rm p}$)

$$n_\nu \cong [1 - (\nu_{\rm p}/\nu)^2]^{1/2}.$$

Collective effects also contribute to κ_ν and should be included (see figure 4).

Multiple scattering from electrons

When the average photon wavelength is comparable with the electron–electron correlation length coherent scattering from the electron distribution can occur. When $\nu \gg \nu_{\rm p}$ the Thompson cross-section (equation (8)) becomes

$$\sigma(\nu) = \frac{3}{8} \int_{-1}^{1} {\rm d}\mu (1 - \mu)(1 + \mu^2) S_{\rm e}(q)$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

$$q = \frac{\nu}{2\pi c}[2(1-\mu)]^{1/2}$$

where $\mu = \cos\vartheta$ and $S_e(q)$ is the electron static structure factor. Correlated scattering from the electron distribution reduces the Thompson cross-section by 27% at the solar center.

Plasma screening and ion correlations

Plasma screening and ion correlational effects in electron–proton bremsstrahlung (equation (5)) can be described through the free–free Gaunt factor. In the (non-relativistic) Born approximation the Gaunt factor can be expressed in the form

$$g_{cor}(\omega) = \frac{\sqrt{3}}{16\pi^3 e^4}\int_0^\infty \frac{dq}{q}\exp\left[-\frac{\hbar^2}{2mkT}\left(\frac{q}{2}-\frac{m\omega}{\hbar q}\right)\right] \times \left|\frac{q^2 V(q)}{\varepsilon(q,\omega)}\right|^2 S_p(q) \quad (10)$$

where $\omega = 2\pi\nu$ is the angular frequency, $V(q)$ is the Fourier transform of the Coulomb potential, $S_p(q)$ is the proton static structure factor and $\varepsilon(q,\omega)$ is the plasma dielectric response function. Similar corrections affect other cross-sections when the density becomes high enough but are not considered in current calculations. In the low-density limit $S_p(q)$ and $\varepsilon(q,\omega) \to 1$, so that equation (10) reduces to the usual Coulomb Gaunt factor.

The effects of plasma dispersion, plasma screening plus ion correlations, and electron degeneracy on electron–proton inverse bremsstrahlung in the solar center are shown in figure 4. Additional dispersion effects appear explicitly in the Rosseland integral (equation (6)). The magnitude of each effect is normalized to the Gaunt factor without these effects included. The corrections are small near $u = 4$ where the largest contributions to the Rosseland integral occur. The reductions in κ_R due to plasma dispersion, screening plus ion correlations, and electron degeneracy are, respectively, 0.4%, 0.7% and 0.8%. Effects of this size are not generally significant, but they are large enough to be of interest in helioseismic and neutrino flux calculations.

Stellar Photometry

Photometry is undoubtedly one of the most fundamental of all astronomical observations. It is hard to imagine any astronomical research of any nature that does not use photometric results in some way or another. The measurement of brightness and of broad-band spectral features in a star or other object's flux output is at the heart of much of what is done in getting the essential data needed for our research problems. All astronomers do photometry or use the results of someone else's observations.

Photometry and spectroscopy are very complementary, as are photometry and theory. In fact, 'complementarity' is one of the most operative words relative to approaches and to progress in our understanding the universe about us.

However, while basically very simple, photometry is very often much misunderstood. To do good research in astronomy, it goes without question that we need accurate and precise photometry of stars and galaxies.

What we measure in photometry is really an integral of the effect of many things: the flux output of the star or other object, including any shells or disks about it (and whatever else nature may have put there to confuse us), interstellar matter, the Earth's atmosphere, the telescope, the filters, the detectors and other things as well. Most of these are changing with time. We are trying to estimate something, perhaps the stellar apparent brightness or some strong feature in its spectrum. We are trying to avoid the adverse impact of other things that may well confuse our understanding. The selection of our observing site, our telescope, our detector and our filters can all impact upon the success of our estimate of the parameter of interest. Photometric systems have usually been designed to be efficient estimators of what we are trying to understand and to avoid the adverse impact of those things that are most likely to cause problems. We try to chose the photometric 'system' that will do the best job. Simple in principle, but often difficult in practice.

Having a good understanding of what is going on is critical. There can and often are adverse effects on our measurements due to stellar rotation, shape of the star, emission, double or multiple stars, line shape, spots, flares, shells, disks, the interstellar matter and its uniformity, variable stellar or emission background, the faintness of our object, atmospheric seeing and variability, clouds, filter leaks and cut-off characteristics, temperature effects and anything involved, detector changes, and so on. With all of this, it seems impossible to think of doing precise not to speak of accurate photometry. In addition, there are issues such as separation of the observed parameters, sensitivity to the feature we are trying to measure, the ease of measurement and reduction and analysis, standard stars and calibrations, reduction methods, information resolution, and so on. How can one manage? It has been done, but not as often as one would like, or even as one thinks.

Precision and accuracy are key issues in photometry, no matter how the photometry is done. This article will discuss some of these photometric issues after laying out the basics of what astronomical photometry is.

A few basics

In astronomy, one is attempting to measure the radiant flux (energy per unit time) coming from an astronomical object, such as a star or a galaxy, generally as a function of wavelength. Such flux measurements can be used in many ways. These applications are beyond the scope of this article on stellar photometry, but in general one can determine the distance to a star, its chemical composition and any peculiarities, its age, whether it varies and how and many other things. Similar information can be obtained about galaxies, and indeed about the interstellar matter in the Galaxy, whether the dark absorbing matter or the bright emission material in nebula. Essentially all methods of determining distance rely on the measure of the object's apparent brightness as we measure it.

If the radiant energy (in joules) is Q, then the radiant flux (in watts), F, is $\mathrm{d}Q/\mathrm{d}t$, the radiant flux at a surface is $\mathrm{d}F/\mathrm{d}A$ (in W M^{-2}), the radiant intensity, I, is $\mathrm{d}F/\mathrm{d}\omega$ (ω is the solid angle through which the flux is radiated, the unit of I is W sr^{-1}, where sr is steradian), and the radiance, E, is $\mathrm{d}F^2/\mathrm{d}\omega\,\mathrm{d}A\cos\theta$, θ being the angle between the line of sight and the normal to the surface considered. Similar terms and units exist for light, rather than the total energy output, and then the unit of luminous flux is the lumen and the luminous flux at a surface is called the illuminance with the unit lux. The unit of luminous intensity is the candela (cd) and of luminance cd m^{-2}. Astronomical photometry, at least in the optical wavelength region, uses its own terminology, the magnitude, discussed below.

One is generally measuring the flux over a range of wavelengths so as to get color discrimination or other such information rather than total brightness. The Earth's atmosphere limits the range of wavelengths that we can observe from the ground from about 320 nm to somewhat beyond 1000 nm.

In astronomy, we measure the brightness in a unit called magnitudes. This unit has its origin in antiquity, when the naked-eye stars were classified by brightness into six groups, called magnitudes. Brightness here means the visual sensation obtained by looking at the star. The brightest stars were called first magnitude and the faintest sixth magnitude. Today we know that the brightest stars are somewhat brighter than that and the best eyes can see fainter than that, when there is no light pollution (man-made sky glow) present. The eye's response to brightness is not linear, but logarithmic. Hence the magnitude scale is logarithmic. In 1856, Pogson defined the modern scale of magnitudes to be such that the ratio between two magnitudes was the fifth root of 100, which is about 2.512. This scale fitted well the ancient scale of magnitudes of stars that had been used for millennia (see also MAGNITUDE SCALES AND PHOTOMETRIC SYSTEMS).

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Hence, a source with an observed flux density of F has a magnitude defined by $m = -2.5\log(F/F_0)$, where F_0 is a standard flux setting the zero point of the scale. It is chosen so as to fit the ancient magnitude scale zero point.

These magnitudes are called apparent magnitudes, for they are what we observe at our telescopes (see below for a discussion of other factors involved, however). The Sun has an apparent magnitude of −26.7, the full Moon of −12.7, Sirius, the brightest star, of −1.5, and the approximate faint limit of the largest telescopes or the HUBBLE SPACE TELESCOPE is about +28.

The intrinsic brightness of the star is called the absolute magnitude, M, and M is defined as the brightness of the star at a distance of 10 parsecs (the parsec is unit of distance in astronomy). $M = m - 5\log(r/10)$. We can see that if we measure m and can in some way determine M (such as from the stellar characteristics we estimate in some other way, often from photometric measurements), we can determine r, the star's distance. In fact, $m - M = 5\log(r/10)$ is called the distance modulus, a logarithmic way of expressing distance to the star (or galaxy). The distance in these expressions is in parsecs, of course.

While the use of magnitudes in astronomy is the standard (for OPTICAL ASTRONOMY, RADIOASTRONOMY uses other more physical units for flux), it has several disadvantages. It is a logarithmic scale, and it is not directly related to any physical units. Note also that a larger value (more positive) of a magnitude means a fainter flux. It also has several advantages. The main one is that it makes it easy to compare magnitude differences between two stars.

The magnitude difference between two stars is $m_1 - m_2 = -2.5\log(F_1/F_2)$. Hence a ratio of 1.001 is a magnitude difference of 0.001, 1.01 of 0.010, 2 of 0.75 (a double-star system in which both components are of equal brightness will look 0.75 magnitudes brighter when both components are observed together, for example), 2.512 of 1.000, 6.3 of 2, 10 of 2.5, 16 of 3, 40 of 4, 100 of 5, 1000 of 7.5 and so on. Note that a ratio of 10^{22} implies a magnitude difference 55, the total range that can be observed in astronomy, as noted above.

Doing photometry

It is possible to consider photometry as the application of the following equation:

$$I(\lambda, t) = c \int (I_s - I_b) IMATPFDO \, \mathrm{d}\lambda$$

where $I((\lambda, t)$ is the flux we observe and c is a normalizing constant; λ is wavelength and t is time. The other terms are discussed one at a time below.

I_s is the item that we are usually trying to determine, the flux from the star (or other object) that we are observing. However, sometimes we are just using a star as a probe to determine something else, such as atmospheric extinction or interstellar reddening values in the direction of observation.

Most of the terms in the above equation are wavelength dependent, vary with time, location in the field of view and with other factors such as temperature, humidity, telescope position, site location and altitude and so forth. Identifying, calibrating and otherwise correcting for all these multitude of adverse effects is critical. The pitfalls for systematic and accidental errors are huge. Errors in any one term can really cause problems. Both precision and accuracy require that these effects all be understood, calibrated and corrected adequately. That takes time and effort, and often such time is not available. Without doing the job right, we are lucky to get the 'right' answer.

$I_s(\lambda, t, x, y, \ldots)$ is the flux emitted by the star we are observing. Here x and y are positions on the sky. This flux can and does include the continuous and line emission and absorption lines, bands, breaks, the effects of any circumstellar material, the effects of duplicity (if any), including the interstellar material around and between the stars, and any and all other effects giving rise to flux originating at or in the vicinity of the star or other object. The star's image is not a point source, and adverse effects can arise from not allowing correctly for the point spread function, including the wings of the image. The image may also be contaminated by adjacent stars, duplicity, or in a crowded field.

$I_b(\lambda, t, x, y, \ldots)$ is the sky background, for which corrections to our observed I_s must be made before we have the 'pure' I_s value. There are many ways to do this, for both photomultiplier and for CCD photometry. Suffice to say here that this correction process is one that can lead to lack of precision and accuracy. In addition to the 'process' itself, we have the problems of variable background (coming from a variable background in space, due to emission regions, absorption regions, crowding of stars in the field, etc) and from effects arising in the telescope (vignetting, etc), from variable sensitivity over the detector, from variable transmission in the filters, etc. For fainter stars, the sky background can even dominate the signal, and that too leads to a decrease in precision and accuracy.

$IM(\lambda, x, y, \ldots)$ is the impact of interstellar absorption (or interstellar reddening, as the absorption is wavelength dependent). Such absorption is likely to present in most observations and must be taken into account. If the reddening law varies in different regions of the sky, as it undoubtedly does, and if the derived corrections for this effect are not well handled, then errors creep in easily. Systematic effects are quite likely to arise.

$A(\lambda, t, x, y, \mathrm{HA}, \mathrm{DEC}, \ldots)$ is the effect of atmospheric extinction, also wavelength dependent. HA is the hour angle and DEC the declination of the observation. Clearly, the effect is also time dependent, over many time-scales. Its determination is not always straightforward. Stebbins is quoted as saying that to determine extinction well, you must spend all your observing time leaving nothing for your program. Probably true. Besides the effects of air mass differences, there are temperature and humidity

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

impacts, inversion level altitude, east–west and north–south effects (and towards–away from a city or mine or whatever), jet trails, light clouds, heavy clouds and so on, all of which change on varying time schedules.

$T(\lambda, t, x, y, \ldots)$ reflects the various things that the telescope and its optics can do to you, including the time and wavelength dependence of the reflective coatings on the optics. There are other effects as well, such as incorrect baffling, vignetting, ghost images, dust, and so on.

$P(\lambda, t, x, y, \ldots)$ are any effects produced by the photometer and its elements, optical or otherwise.

$F(\lambda, t, x, y, \ldots)$ is the impact of the filter (or other wavelength discriminator) on the throughput. It is our choice of FILTERS (or spectrometer) that gives us our information resolution. The careful choice of filters is critical to success, for many reasons. However, as in so many other items noted here, filters are wavelength dependent in themselves, and that dependence changes with time, temperature, humidity, dust coverage and other perverse reasons. One must be aware of all of this, and allow for it if necessary. It is necessary. The detailed transmission curve of the filters must be known, and allowed for. Central wavelength, shape, bandwidth, tails, are all important items.

$D(\lambda, t, x, y, \ldots)$ is the impact of the detector. Problems also can and do exist with photomultiplier, CCD, and other types of photometry.

$O(\lambda, t, x, y, \ldots)$ is the impact of 'all other'. There are always some of these. Identifying and allowing for them is the key. Here we might well include any effects produced by differing reduction procedures.

Problems in doing photometry

With all these potential and real problems, it is a wonder that one can do photometry at all. The pitfalls are so many. The time needed to investigate all of them is necessarily large, and not often available. Factors change with time as well, often on a rather fast time schedule, or discontinuously. Is there no hope? Probably there is. After all, good photometry has been done. But there is no way it can occur without careful attention to all the details, not just to getting the data and using a neat reduction package (see SOFTWARE: STELLAR PHOTOMETRY). There is a lot more to it.

A real understanding of what is going on is difficult or impossible. It is critical to understand and allow for all the issues involved.

Standard photometric systems

It is hard to imagine doing much in astronomy without a measure of brightness or color or other photometric parameters. To be able to do effective research programs, it is essential to be able to compare the photometric data used with other such data. Hence, we all use standard photometric systems, such as UBV, or $uvby\beta$, or Geneva, or Vilnius standard systems.

The section above discussed the factors involved in $I(\lambda, t)$. A photometric system is one that uses these factors, particularly the term F (filter), to define one or more wavelength regions to measure. These are chosen to give the observer a number of parameters that can be related to stellar (or other) characteristics, such as brightness in a limited wavelength range, 'color', chemical composition, temperature, effects of the intervening interstellar material on the star's flux, and so on. Quite a number of such photometric systems have been defined and used over the years. Only a few will be mentioned here.

Visual magnitude

The magnitude as 'measured' or seen by the eye. The eye has a certain spectral sensitivity, and that defines the wavelength region of the magnitude system. Since eyes vary, from individual to individual and with time, and indeed even with the level of incoming flux, this is not a precisely defined system. But it has been and still is a most useful one. It is how bright we see the stars. It has also been defined in a more precise way, using filters and detectors other than the eye, and in a way so as to match the estimates that have been made by observers using only the eye (often supplemented by a telescope).

Photographic magnitude

With the advent of photographic plates, there of course came definitions of a photographic magnitude, brightnesses as measured with a photographic plate. Even more than with the eye, photographic emulsions vary in wavelength sensitivity, so accuracy often suffered. Most emulsions were more blue sensitive than the eye, so the combination of the two magnitudes could give a measure of 'color', the ratio of brightnesses at two different wavelengths.

UBV system

The advent of electronic detectors revolutionized photometry. They allowed much more precise photometry, and with much greater sensitivity than the eye or photographic plates. The wavelength sensitivity also became better, and we now have magnitude systems ranging from the ultraviolet (indeed, even for shorter wavelengths, as observed from above the Earth's atmosphere) to the far infrared. The initial systems were patterned after the visual and photographic ones, but later ones broadened the range, adding more filters and more wavelengths (see also DETECTORS: PHOTOGRAPHY). There were many, but the most used one came into widespread use soon after the introduction of the photomultiplier tube. It uses three bandpasses, one matching the visual magnitudes, one in the blue roughly matching the old photographic magnitude and an additional one in the ultraviolet. They are called, naturally, V, B and U, and the system is the UBV system.

It is a natural system in two ways. Firstly, the band passes fill the region of sensitivity of the photomultiplier tubes used, from about 320 nm to 600 nm, dividing this region into three magnitudes, the U, B and V. Each bandpass is about 100 nm wide. Second, these bandpasses offer a great deal of information about the star's (or other object's) flux output. V gives a visual magnitude that

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

tells us the star's apparent magnitude. B gives another band and the two define a 'color index', B–V, that can be used to estimate the star's temperature (and other things sometimes), U and B also give a color index, U–B, that offer another parameter useful to estimate stellar characteristics, such as chemical composition, interstellar reddening, and absolute magnitude. We have three parameters that can be used for our research, V, B–V and U–B. Naturally, it is difficult to estimate more than three stellar characteristics with only three parameters, but sometime it can be done. All such applications are beyond the scope of this article. The point to be remembered here is well sketched out above, in the discussions of pitfalls. In later years, with the advent of detectors sensitive in the red region of the spectrum, additional wide-bandpass magnitude systems were developed to supplement the UBV system, in particular R and I magnitudes, for red and infrared regions.

uvby system, or Strömgren system

A natural extension of the UBV system was to fill the region of sensitivity of the photomultiplier tube with four band passes instead of the three of the UBV system. Strömgren proposed such a system and it has had widespread usage. It offers additional 'information resolution', and overcomes several of the observational problems of the UBV and other such wide-band systems. It is an intermediate bandpass system, with each filter being about 20 to 30 nm wide. The y magnitude can be related very well to the V magnitude. The color index $b - y$ gives a measure of temperature. One defines two 'color differences'. The first, $m_1 = (v - b) - (b - y)$, gives an estimate of the 'blanketing' due to metallic absorption lines in the region of the v band. The second, $c_1 = (u-v)-(v-b)$, gives a measure of the increased absorption in the ultraviolet, due in most stars to the continuous absorption of the hydrogen. This can be related to absolute magnitude in some stars, and to other characteristics as well. With four parameters, one can usually do a better job of estimating key characteristics of the star's energy output. Again, it is beyond the scope of this article to discuss how to use these photometric parameters for research. Sufficient to say that they are widely used, and are one of the main keys to our understanding of stellar structure and evolution, and to the geography of our galaxy and of the universe.

Narrow band systems

It is possible to develop additional systems, of any band width. Narrow band systems can be used to estimate the strengths of absorption or emission lines or of other features in the spectrum. One, for example, measures the strength of the hydrogen Hβ line, a parameter related to temperature in some stars and to absolute magnitude in others. It gives another parameter to supplement either the UBV system or the $uvby$ system. Many other such standard systems have been developed, and a few are widely used.

Systems with CCD detectors

The recent advent of CCD (CHARGE COUPLED DEVICE) detectors has been a big jump forward. Their efficiency is very good, and they are areal detectors as opposed to the single-element photomultiplier. Hence, one can work fainter for a given precision, and do it over a area not just for a single object. They combine the best of the photographic plate and the photomultiplier. They have many advantages therefore, but also some disadvantages. They are much more sensitive than either the photographic plate or the photomultiplier tube. One can save the electronic image for later processing. They respond to light linearly, like the photomultiplier tube. They have relatively low background noise. But the cost is high, of both hardware and analysis tools. The field size is smaller than the photographic plate (though increasing, especially through the use of mosaic detector arrays (but at high cost)), and processing and analysing the images is very time complex and time consuming. As in all photometry, great care must be taken to ensure precision and accuracy.

Bolometric magnitude and absolute intensity measurement

Two other types of photometric systems should be mentioned. The first is the bolometric magnitude. This is the magnitude measured over all wavelengths. It cannot be measured directly, due to the absorption in the Earth's atmosphere and due to the difficulty of having a detector with such a range of sensitivity. Its value is that it is an estimate of the total flux output of a star. The second is the measurement of absolute intensities, rather than relative or differential intensities. Clearly, all the systems discussed above are differential, relative to some standard stars or zero point. It is of value to measure also, though very difficult, the absolute intensity in physical units. With such a measurement for a few well chosen stars, the other systems can then be put on an absolute scale. Such a transformation is essential for comparisons with theoretical calculations of stellar flux, for example.

Standard stars

It is not always clear to the user how such standard systems have been defined or are to be matched, or even how they are to be used. Is it by the careful choice of filters and detector that match the system? Perhaps, but that can be very difficult if not impossible. We don't use the detectors that were used to establish the system originally, for example. Is it by careful choice and observation of a subset of the standard stars that were used to help establish the system? Sometimes, but sometimes not. Sometimes not for a good reason: they are all too bright for our current telescope and detector system, or there are no standards of the stellar type we need. Sometimes not for a bad reason: not everyone has the concept of interpolation well in mind, or we don't have the time to do an adequate job.

In some sense, viable photometric systems are rather like the MK spectral classification system: they depend a great deal on the usage of standard stars. We can (and should) do the best we can in the choice of spectral

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

wavelengths and bandwidths for the filters and in our choice of detectors and reduction procedures, but the final quality and value of the system will depend a lot on the quality of the standard stars used to help define the system and on the choice of standards used for any observing program with the system. Such standards must span the range of stellar types that will be observed with the system and on the specific observing program. Naturally, the standards must be observed and tabulated with high precision and high accuracy. Many examples exist in the literature of problems that arise when these obvious guidelines are not followed. Considerable effort should be made by all photometrists to ensure that an adequate set of standard stars exist for the most used standard photometric systems.

One must select an adequate number of standards of the needed characteristics to ensure a good job of interpolation in all phases of the observation and reduction process. This may not be easy to accomplish, especially if we are observing either a wide range of 'unknowns' or types of objects for which few if any standards exist. In the first case, a rule may be 'the more the better'. In the second case, one may have to try to develop substandards of the type of characteristics needed.

In the observing itself, one must observe so as to interpolate. This means that one must be observing standards at somewhat higher air masses (and lower) than any of the unknowns. One must start and end the night with standards, and intermingle them throughout the night. Particularly on 'all sky' programs, it is helpful if one can randomize the intermixing of standards of different characteristics, so that no pattern is built in that may later cause systematic problems.

Careful and adequate time spent planning the observing program is essential, and will always pay off in increased accuracy. So will adequate time spent observing standard stars, even in the face of time pressures (not enough nights assigned to the program, equipment problems, clouds, and learning curve time). Good equipment (stable and well understood) is essential as well. And a most valuable asset is a quality observing site.

Here are some of the problems facing us in the future:

(a) Getting adequate observing time to do our programs, and to observe standards (and other calibrations). The excitement of the field and the increasing number of astronomers (in spite of the funding problems we all face) coupled with the fact that some of the telescopes useful for photometry are actually being closed down means that the pressures on time will only increase.
(b) Hence, the time available to investigate standard systems and to continue our efforts to establish more standards (especially ones of additional characteristics, including fainter ones of all types) will be sadly lacking.
(c) Equipment is getting more powerful but more complicated. We are getting separated even further from the sky than we have been in the past. It will be harder to understand the content and the performance of our black boxes, both hardware and software ones.
(d) The drive to work fainter and to observe strange and wonderful objects means that the extrapolation aspects of photometry may be more in evidence than good astronomy requires. Even photometrists get off the track; imagine what others will be doing.

The future

What about the future? If all goes well, and it seldom does, we might see:

(a) New technology, detectors and instrumentation, new telescopes, including new generation small ones, an essential component in a balanced funding approach to astronomy. We need it all, and we will be getting some of it without question.
(b) Better understanding of photometry and photometric systems.
(c) More and better data. And adequate archiving of the data.
(d) More and better standard stars. More tie-ins.
(e) A wider range of standard stars, in character and faintness.
(f) Better astronomy, better science. Precise and accurate photometry is fundamental to it all.

Summary

Photometry has always been of the highest value in astronomical research. It always will be. Such photometry must be of high precision and accuracy. The key is to understand the basic principles of photometry, and of the potential pitfalls involved. The existence of well chosen standard systems and standard stars, both for their applicability to the research job and for their intrinsic merit, is one of the most powerful tools to ensure that reality.

Stellar Populations

A stellar population is a set of stars of the same age and chemical composition. Born together at some point in the Galaxy, stars of the same stellar population will share the same kinematic properties in the Galaxy, whether those be their circular velocity with respect to the Galactic center or their random velocity in the Galactic halo.

Examples of such simple stellar populations are the stars of the ORION population (Herbig and Rao 1972) (figure 1), the nearby OB ASSOCIATIONS (de Zeeuw *et al* 1999) and the GLOBULAR CLUSTER 47 Tuc (figure 2). We can collect all the simple stellar populations of roughly the Sun's age and call them the old disk population (Eggen *et al* 1974), or all the simple stellar populations of the central predominantly old regions of the Galaxy and refer to them as the bulge population or the more diffuse collection of high velocity stars in random motion in the Galaxy's potential and refer to them as the halo population. It is easy to see that a stellar population is a very broad collective term for a sample of stars with what can be, but need not be, well-defined statistical kinematic, age and chemical composition properties.

The linkages between old stellar populations were originally made by Baade (1944). The prior history of the subject and its later development are recounted by Sandage (1986), who notes 'The main thrust and the ultimate aim of the work in stellar populations today is to achieve an understanding of the formation and development of galaxies with time'.

In the broader extragalactic context the concept of a simple stellar population is immensely useful, and nowhere more so than in population synthesis, the process of constructing a model of a galaxy from its constituent stellar populations (see SYNTHETIC STELLAR POPULATIONS). In population synthesis a galaxy is the sum of its stellar populations of a particular age, weighted by the star formation rate (SFR) at that epoch. For example, one can model a Magellanic irregular galaxy as the sum of MAGELLANIC CLOUD star clusters of every age, t, from a million years to ten billion years, weighted by SFR(t). Of course, a galaxy will also take a particular path through its chemical enrichment history, $Z(t)$ (where Z is the heavy element abundance by mass). Therefore, population synthesis must also deal with this complication. Other complications are conceivable too, such as a changing initial mass function. The formalism for dealing with simple stellar populations in this way is elegantly developed by Renzini and Buzzoni (1984).

Star formation history

In principle the color–magnitude diagram of a stellar population bears a full record of the star formation history (SFH) of that population. There has been considerable progress in recent years in extracting the desired information from the data. The theoretical underpinnings are described by Renzini and Buzzoni (1984).

Figure 1. The Orion Nebula, our closest sample of a young stellar population, courtesy M Bessell, RSAA, ANU.

Figure 2. The globular cluster 47 Tuc, courtesy AAO.

The main sequence

When stars are formed, they are laid down on a long-lived hydrogen-burning main sequence (MS), following what approximates, but is unlikely to be exactly, a universal initial mass function (a distribution function). The stars then evolve away, starting with the most massive ones, with lifetimes which are a (weak) function of metallicity. The present-day mass function would therefore be invertible to a SFH, SFR(t), if $Z(t)$ were also known, at least approximately. In practice, the observable is a luminosity function (LF), rather than a mass function, but the mass–luminosity relation makes the LF a good substitute, unless unresolved binary stars distort the LF seriously (see LUMINOSITY FUNCTION OF GALAXIES). The solar neighborhood (Twarog 1980), the Large Magellanic Cloud

Figure 3. The LMC, courtesy M Bessell, RSAA, ANU.

(LMC) (figure 3) and the Galactic bulge have been good laboratories for this approach to learning the SFH. To zeroth order the solar neighborhood is a constant-SFR population, the LMC is characterized by a recent burst and the bulge shows a prominent initial burst. Thus a simple range of possibilities has now been explored.

The giant branch

Because of the mediating effect of their envelopes, giant branches are sensitive to chemical composition and are relatively insensitive to age (see also CHEMICAL COMPOSITIONS OF STARS). The stellar populations of early-type galaxies are dominated by their light. Nevertheless, post-MS stages of stellar evolution do provide tracers of the SFH in stellar populations in an indicative manner, if not in the more rigorous way that the MS offers. Often this is all that is available.

Useful tracers of young, intermediate-age and old stellar populations are as follows:

Age (yr)	10^8	10^9	10^{10}
Tracer	tip of MS	upper AGB	tip of RGB

The red giant branch (RGB) tip is where the helium flash ignites in low-mass stars at around 2000 solar luminosities (M_I −4 mag; Ferrarese *et al* 2000). The asymptotic giant branch (AGB) is the second ascent of the giant branch with a characteristic bolometric luminosity of −5.5 mag for 1 Gyr old stars. In populations more metal poor than the Sun, upper AGB stars are CARBON STARS (Mould and Aaronson 1986, Frogel *et al* 1990) and readily recognizable.

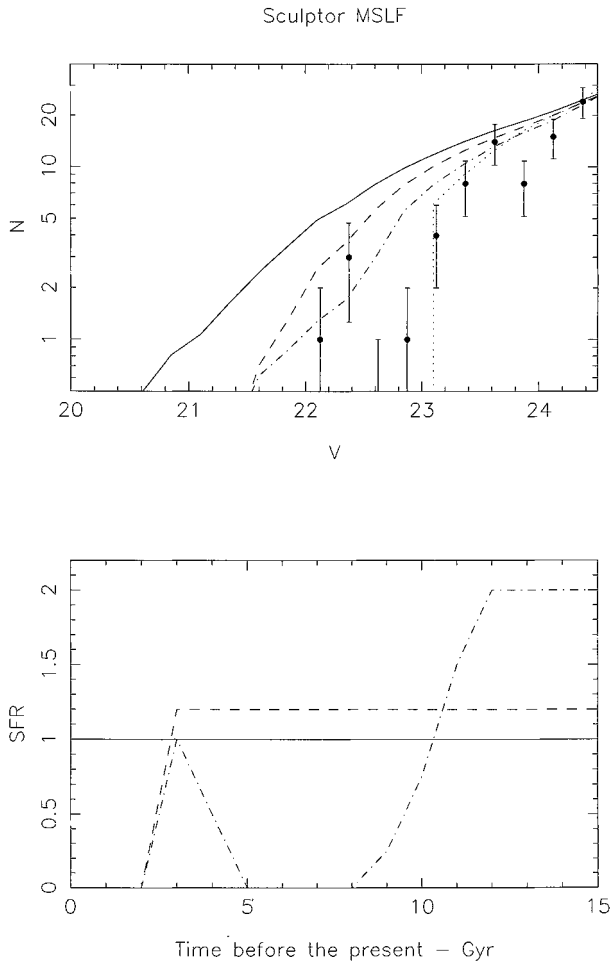

Figure 4. MS luminosity function for the field studied by Monkiewicz *et al* (1999). We can fit the Sculptor MS with a variety of SFHs, as outlined in the lower part of the figure. The dotted curve is a simple stellar population of age 15 Gyr, i.e. a delta function in the lower plot.

Determining SFH

These tracers can suggest a coarse SFH for resolved galaxies (e.g. LGS 3, Mould 1996) with the aid of Renzini's fuel burning theorem:

$$n = B(t)Lt$$

where L is the luminosity of the system, t is the lifetime of the tracer population and n is the number of tracer stars. B is a slowly varying function of age.

A coarse SFH can be graphically illustrated as in figure 4. Hodge (1989) calls these diagrams 'population boxes'. Population boxes for LOCAL GROUP DWARF GALAXIES have been compiled by Mateo (1998). He finds (1) that no two of these galaxies have the same SFH, (2) that many dwarf irregular galaxies contain significant old populations (e.g. IC 1613, NGC 6822), (3) that most recent star formation episodes are short (10–500 million

years in duration), (4) that red horizontal branches are common in metal-poor systems (the 'second parameter effect') throughout the Local Group, (5) that there are no purely old galaxies (with the possible exception of the Ursa Minor dwarf spheroidal) and (6) that intermediate-age galaxies exist (e.g. M32 and Leo I).

For accurate SFH determination synthesis of the color–magnitude diagram can be done. Full population synthesis is described by Tolstoy (1995). A method of maximum likelihood multi-isochrone fitting has been developed by Han, Hoessel and Gallagher (private communication).

Stellar Pulsation

Pulsating stars are a subtype of variable stars that vibrate, and these vibrations cause their brightness to vary. The brightness varies because of the changing area and temperature of the surface layers (see VARIABLE STARS). The vibrations are due to regulation of the outward radiant energy flow. Pulsating stars are ubiquitous in that they can be found almost everywhere in the Hertzsprung–Russell (H–R) diagram, although conspicuous pulsations are present in more limited portions of the H–R diagram, as shown in figure 1. In addition to their intrinsic interest, pulsating stars have played an important role in advancing our understanding of physics and the universe.

Fabricius discovered the first repeating variable star in 1596, and it was later called 'Mira', which means 'wonderful', because of its changing brightness. By coincidence, Mira is a pulsating star and the prototype of the MIRA VARIABLES. More important was the discovery of periodic light variations of δ Cephei in 1784. This star is now the prototype of the pulsating yellow supergiant stars called Cepheids. Cepheids are historically the most important class of variable stars, because they follow a CEPHEID PERIOD–LUMINOSITY RELATION, first discovered by Henrietta Leavitt in 1912. The period–luminosity relation reveals that Cepheids with longer periods are intrinsically more luminous (have brighter absolute magnitudes), based on Leavitt's study of a large number of Cepheids in the Magellanic Clouds. Later, E Hubble discovered Cepheids in the Andromeda galaxy, and the period–luminosity relation enabled him to determine the distance, placing it well outside our own Milky Way. This application makes Cepheids vitally important 'yardsticks' for measuring the distances to nearby galaxies (see UNIVERSAL DISTANCE SCALE). One of the motivations for building the Hubble Space Telescope was to detect Cepheids in the VIRGO CLUSTER of galaxies to provide a reliable distance calibration for use in determining the size of our universe. There is a growing impression that most, if not all, stars pulsate—if measured carefully enough—and the maturing field of astroseismology takes advantage of the fact that each independent pulsation mode offers a probe of the star's interior. Stellar astronomers are now in a position to determine the interior structure of stars directly, and to a level of detail unforeseen a generation ago.

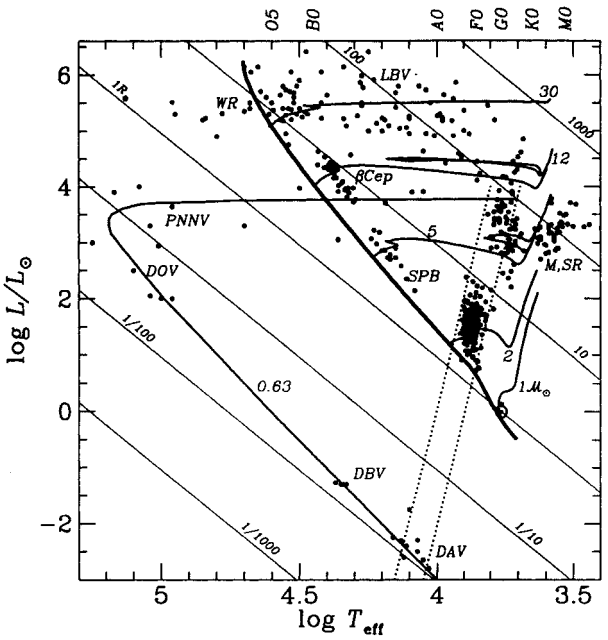

Figure 1. A 'pulsating' Hertzsprung–Russell diagram with the location of important variable star classes listed. Representative evolutionary tracks are also plotted with the stellar mass (in solar units) indicated near each track. Slanted lines are labelled with the star's radius (in solar radii). Pulsating star classes labelled here include: luminous blue variables (LBVs), β Cephei stars (βCep), planetary nebula nucleus variables (PNNVs), pulsating PG 1159 stars (DOV), slowly pulsating B stars (SPB), Mira and red giant pulsators (M,SR), and pulsating DB and DA white dwarfs (DBV and DAV).

A brief history of stellar pulsation

After the discovery of Mira in 1596 and the establishment of its periodicity by about 1660, the pace of discovery of variable stars was slow. Only about 20 variable stars were known by the 1840s; about this time, F W A Argelander and J Herschel put the search for variable stars on a more systematic footing. The advent of astronomical photography, and in particular, the Harvard Observatory photographic patrols, begun in about 1890, provided a permanent record of stellar brightnesses and a systematic coverage of the sky. The Magellanic Clouds and rich star fields of the southern Milky Way added many new variable stars, so that thousands were known by 1912, when H Leavitt discovered the Cepheid period–luminosity relation.

While the discovery of variable stars accelerated in the 1860s, Lord Kelvin laid the theoretical framework for non-radial oscillations of liquid spheres in 1863. However, it was not until 1879 that A Ritter suggested radial pulsations, coupled with temperature variations, as an explanation for the light variations of some periodic variable stars. In spite of this, it was not until 1914, when H Shapley proposed oscillations of the star's surface (pulsations) as being responsible for Cepheid variability, that pulsations were seriously considered. By 1918, A S Eddington laid the mathematical foundations for stellar pulsation theory, and consequently directed much of the theoretical work towards considering radial pulsations as the explanation for stellar pulsations for the next 50 years or so.

Although radial pulsation theory replicated many observational properties of Cepheids, the source of pulsation driving was not determined until the 1950s, when J P Cox and S A Zhevakin independently proposed that cyclical partial ionization of He^+ to He^{2+} was responsible for the observed pulsations. Subsequent linear

and nonlinear calculations confirmed this hypothesis. Digital computers started to become available by the 1960s, and with these people were able to calculate pulsation periods from the linearized pulsation equations as well as nonlinear hydrodynamic simulations for increasingly realistic stellar models. By the 1970s and early 1980s people once again began to consider non-radial pulsations, in response to observations of stars that pulsated with too many modes in a given frequency range to be explained only by radial modes. Also, observations of the variable white dwarfs and the β Cephei stars revealed pulsation periods and radial velocity curves that could only be explained by non-radial oscillations.

In the last ten years, the advent of ever more powerful computers and CCD cameras is making theoretical calculations and high-precision observations of pulsating stars increasingly accessible (see CHARGE-COUPLED DEVICE). Observers also took a cue from helioseismology and started to look for stars that pulsate in many modes to perform astroseismology on them. This necessitated the creation of multilongitude multisite observing networks that can continuously observe a target star for days at a time in order to reduce spectral leakage 'aliasing' in Fourier transforms caused by data gaps. White dwarfs and δ Scuti stars are leading the way in terms of astroseismological potential and multilongitude observations. Finally, CCD survey projects designed to look for gravitational MICROLENSING are turning up large numbers of newly discovered pulsating stars, often without previous biases or selection effects that mar a statistical understanding of instability strip boundaries and/or the incidence of pulsating stars within a given instability strip. The present era of precision instrumentation and abundant computational resources is ushering in a new understanding of the internal structure of pulsating stars and a clearer picture of why they pulsate, which we describe below.

Some aspects of the theory of stellar pulsation

Cepheid variable stars obey a period–luminosity relation to considerable accuracy, and this has a rather simple physical explanation. First, we know that Cepheids are radial pulsators (their motion is strictly in and out), and we can approximate the period of a radial mode as the time it takes for a sound wave to travel from the surface to the center and return

$$\Pi = \frac{2R_\star}{c_s}$$

where c_s is the average sound speed and Π is the pulsation period. Elementary physics texts show that the adiabatic sound speed is $c_s^2 = P\Gamma_1/\rho$, and we can use hydrostatic equilibrium to determine that

$$\Pi \approx (G\bar{\rho})^{-1/2}$$

where $\bar{\rho}$ is the mean density of the star and $\Pi(= 2\pi/\sigma)$ is the pulsation period. The latter expression is called the *period–mean density relation*. Most Cepheids have spectral type between F5 and K0, corresponding to effective temperatures between 7000 and 5000 K. The fairly narrow temperature range occupied by Cepheids implies that the more luminous Cepheids are brighter mainly by virtue of being larger. The most luminous Cepheids have radii about 10 times larger than the least luminous ones, but the most luminous Cepheids are only about four times as massive. This implies that the mean density of a luminous Cepheid is about 1/250 that of a less luminous Cepheid and thus their periods should be about 20 times longer. This agrees reasonably well with the observed period range of Cepheids in our galaxy, which lies between about 2 and 100 days.

Radial pulsations turn out to be a special subset of the more general non-radial pressure modes (also called p-modes), where pressure is the restoring force. In everyday life, these are the sound waves we hear when talking or playing the radio. In this scheme, radial modes have a spherical harmonic index (ℓ) of zero, while p-modes in general can have any positive value of ℓ, and although their motion is predominantly radial, there is some horizontal motion as well. Several features of p-modes are particularly useful in the analysis of stellar pulsation observations and are derivable from the expression for p-mode frequencies in the limit of very high overtone number (the number of times the eigenfunction crosses zero). The general expression for the frequency ($\sigma_{n,\ell}$) is

$$\sigma_{n,\ell} \approx 2\pi\nu_0(n + \ell/2 + \epsilon)$$

where

$$\nu_0 \equiv \left(2\int_0^R \frac{1}{c_s}\,\mathrm{d}r\right)^{-1}$$

n is the *overtone number* and ϵ is a small constant that depends on the structure of the star. There are four useful facts we can derive from these expressions. First, for a given radial overtone number, the frequency of a p-mode increases with ℓ. Second, the p-mode frequency also increases with n. Third, in the asymptotic limit of very high overtone number, the frequency spacing for consecutive overtone p-modes of a given ℓ is constant; this works quite well in general for all but the lowest overtones. Finally, the p-mode frequencies for modes of different ℓ follow the trend set by

$$\sigma_{n,l} \approx \sigma_{n-1,\ell+2}.$$

Non-radially pulsating stars can also pulsate in g-modes, where buoyancy rather than pressure, is the restoring force. The motions tend to be more horizontal than radial, so that material sort of 'sloshes' back and forth. Buoyancy is what causes a cork to bob up and down in water after it has been pushed down, and the natural frequency of oscillation is expressed in terms of the Brunt–Väisälä frequency

$$N^2 = -g\left(\frac{1}{\rho}\frac{\mathrm{d}\rho}{\mathrm{d}r} - \frac{1}{\Gamma_1 P}\frac{\mathrm{d}P}{\mathrm{d}r}\right)$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

where N is the Brunt–Väisälä freqency, g is the local gravitational acceleration, and Γ_1 is one of the adiabatic exponents, given by

$$\left(\frac{\mathrm{d}\ln P}{\mathrm{d}\ln \rho}\right)_{\mathrm{ad}}.$$

An approximate expression for the pulsation frequencies of g-modes is

$$\sigma_{n,\ell} \approx \frac{[\ell(\ell+1)]^{1/2}}{n\pi}\int_{r_b}^{r_a}\frac{N}{r}\,\mathrm{d}r$$

where r_a and r_b are the upper and lower boundaries of the g-mode propagation region. Like the p-modes, g-modes also have useful limiting behavior in the limit of high overtone number. First, the period increases with increasing overtone number n, and the period spacing between consecutive overtone modes of a given ℓ is constant, to a good approximation. Finally, the periods of g-modes with different ℓ, but the same overtone number are related by

$$\sqrt{\frac{\ell_1(\ell_1+1)}{\ell_2(\ell_2+1)}}$$

so that the period of the nth overtone $\ell = 1$ mode is about $\sqrt{3}$ times longer than the analogous $\ell = 2$ mode, and so on.

The previous discussion treats the existence of pulsations as a given, whereas in reality stars must somehow excite their own pulsations. The vast majority of pulsating stars act as a heat engine, and in their outer layers, ionization and recombination of a dominant ion species acts to store and release the outward flow of energy on a periodic basis. Normally, an increase in radiant energy flowing outwards in a star will increase the temperature, decrease the opacity (a measure of resistance to radiant energy flow), and allow the radiation to escape more easily. Thus, under normal conditions, such as in fully ionized material, the change in opacity favors pulsational *stability*. In a partial ionization zone, however, an increase in radiation flow can be absorbed by the ions, resulting in an increase in the fraction of ions present, rather than increasing the temperature of the material. As a result, the radiant energy flow gets dammed up and stored as ionization energy; this mechanism is called the γ mechanism. In addition, partial ionization zones also produce strong opacity gradients, and the region can drive pulsations if

$$\frac{\mathrm{d}}{\mathrm{d}r}\left(\kappa_T + \frac{\kappa_\rho}{\Gamma_3 - 1}\right) > 0$$

where

$$\Gamma_3 - 1 \equiv \left(\frac{\partial \ln T}{\partial \ln \rho}\right)_{ad} \qquad \kappa_T \equiv \left(\frac{\partial \ln \kappa}{\partial \ln T}\right)_{\rho}$$

$$\text{and} \qquad \kappa_\rho \equiv \left(\frac{\partial \ln \kappa}{\partial \ln \rho}\right)_{T}.$$

Regions satisfying the previous inequality are unstable to the opacity (or κ) mechanism, and the radiant energy blocked by this opacity increase is then converted into kinetic energy of the oscillations. In most cases of interest, the κ and γ mechanisms work together. Figure 2 shows a diagram of a typical pulsation cycle.

While the κ and γ mechanisms are capable of modulating the outward energy flow from a star, certain conditions must be met before the star can modulate the energy flow effectively and become a pulsating star that we can observe. First, the driving region needs to make the structure of a star 'overshoot' the equilibrium state so that the pulsations have a chance to grow in amplitude. For this to happen, the driving region must still be gaining heat at the instant of maximum compression. Then, when the star starts to expand, the heat release adds an extra 'push' to the outer layers, causing the star to expand past the equilibrium state. An analogy would be a swinging, frictionless pendulum; one must apply an extra nudge after the highest point of the swing to add to the kinetic energy of the pendulum in order to make it swing in a wider arc. The second condition is that the energy flow must be modulated with a period similar to a natural eigenmode of the star; in other words, the thermal timescale of the driving region needs to be roughly equal to the pulsation timescale, which may be expressed by

$$\frac{C_v T (\Delta m)_{\mathrm{tr}}}{L} \approx \Pi$$

where Δm_{tr} is the mass of the star from the surface inwards to the 'transition region', C_v is the heat capacity per unit volume and L is the stellar luminosity. C_v, T and L are time-averaged values at the 'transition region'. In typical stars, the 'transition region' is quite near the surface; typically at about $10^{-8}M_\star$ to $10^{-10}M_\star$ inwards from the photosphere. For an He^+ to He^{2+} region, the temperature is about 50 to 100 000 K.

Classes of pulsating stars

Pulsating stars can be found in many parts of the Hertzsprung–Russell diagram as shown in figure 1, and opacity mechanisms are responsible for essentially all of the observed pulsations (see HERTZSPRUNG–RUSSELL DIAGRAM). He^+ to He^{2+} ionization is responsible for the pulsations of the best-known pulsators, such as the Cepheids, RR Lyrae and δ Scuti stars, which occupy a sloping band in the H–R diagram. Several new classes of variable stars and increasing numbers of stars in previously known classes have been discovered over the last 20 years, mainly due to increasingly sensitive observational techniques. Given the apparent ubiquity of stellar pulsations across the H–R diagram, there is some reason to suspect that possibly *all* stars pulsate, and the only question is 'at what amplitude?'. In the next paragraphs, we describe most of the major classes of pulsating stars and their astrophysical context (see table 1).

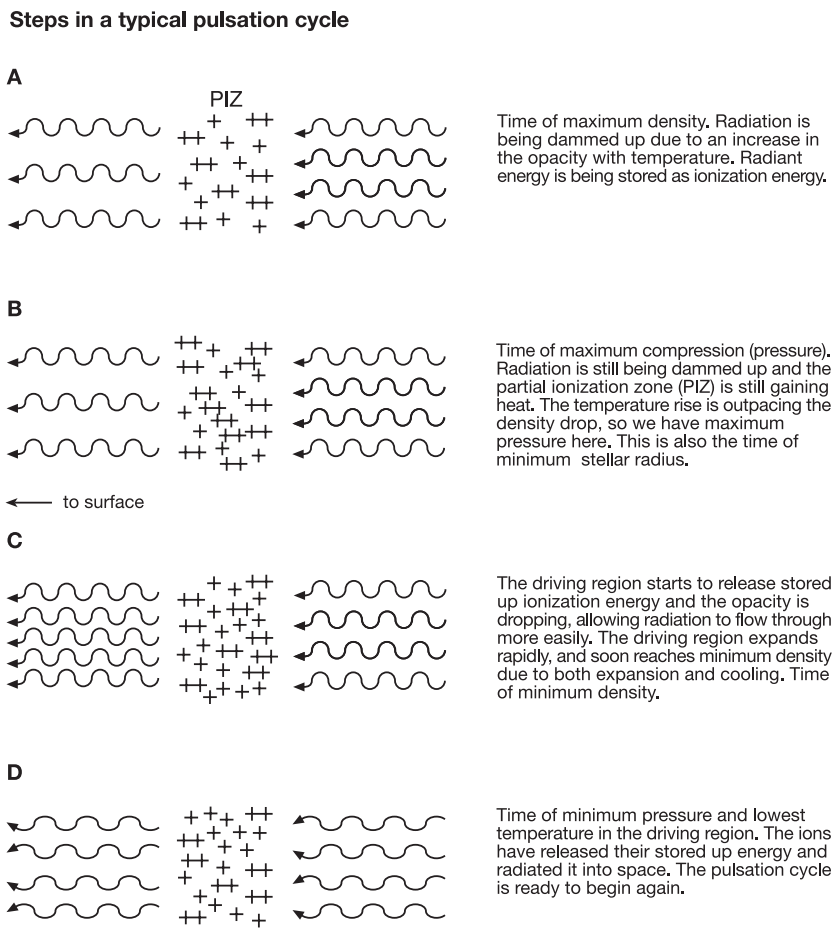

Figure 2. A schematic diagram of the driving region in a star pulsating via the κ mechanism. Panel A: As the star compresses, outward radiation flow gets blocked due to an increase in opacity. Radiation energy is stored in the ions and kinetic energy. There is relatively little increase in temperature. For reference, we will call this the time of maximum density. Panel B: This panel shows the point of maximum compression (pressure). Radiation is still dammed up and the region is still gaining heat, but the density is dropping due to increasing temperature. Panel C: The driving region is expanding and is getting an extra push due to the release of stored up ionization energy. The opacity is dropping as the material expands, which helps the radiation flow out more easily. This is the time of minimum density, which is the result of both material expansion and temperature decrease. Panel D: At maximum expansion, the material is still losing heat and reaches its minimum pressure. All of the stored up energy is released by the ions (but the material is still partially ionized), and the pulsation cycle is set to start again.

Cepheid variables

Cepheid variables were among the first pulsating stars to be discovered, and their well defined period–luminosity relation, coupled with their high luminosity, makes them valuable 'standard candles' for measuring distances to other galaxies out to about 20 Mpc. The prototype star is δ Cephei, and all of these stars pulsate in one (or two) radial modes (typically the radial fundamental mode) that have very precise periods that range between 2 and 100 days. Cepheids are yellow (F to G) supergiants with masses between 5 and $20M_{\odot}$ and luminosities between 1000 and $100\,000L_{\odot}$. Most are core helium burning objects, although some could be burning hydrogen in a shell around the helium core as they evolve to become red giants for the first time. The typical Cepheid light (or radial velocity) curve has a steep rise to maximum amplitude that takes about 0.2Π and a more gradual decline, but the exact shape of the curve depends on the period, as first noticed by E Hertzsprung in 1926 and illustrated in figure 3. For periods less than 6.5 days, the curves appear smooth, but between 6.5 and 9 days, the curves show a bump on the descending part of the curve that moves towards maximum amplitude as the period becomes longer. Between 10 and ~15 days, the bump then appears on the ascending part of the curve. The theoretical explanation for this phenomenon did not appear until the 1980s, when J R Buchler and collaborators demonstrated that the bump is the result of a 2:1 resonance between the radial fundamental and the radial second overtone mode. In addition to computing theoretical light curves that compare well with observations when the resonance effects are included, the theory also replicates the observed

DA white dwarf	DAV	$\sim$ 11	$\sim$ 0.6	$\sim 10^{-3}$	100 to 1200 s	NR(g)
Luminous blue Variables	LBV	$\sim$ 20	30 to 100	10^5 to 10^6	$\sim$ 30 to 50 d	NR ?
R Corona Borealis	R CBr	5.0 to 7.0	$\sim$ 1	$\sim 10^4$	$\sim$ 40 d	R?
Subdwarf B stars	EC14026	29 to 35	$\sim$ 0.5	20 to 40	100 to 400 s	NR(p)

†Mode types: R stands for radial pulsations, while NR stands for non-radial pulsations. (p) stands for p- or pressure modes, while (g) stands for g- or gravity modes.

properties of the light curves when they are decomposed into a Fourier expansion of sine waves.

W Virginis stars

The *classical* Cepheids are Population I objects, whereas W Virginis stars are low-mass ($\sim 1 M_\odot$) analogs that are evolving towards the asymptotic giant branch (AGB) or are engaged in thermal pulses off the AGB. They are also called 'population II Cepheids' and/or 'type II Cepheids'. Like the Cepheids, the W Vir stars also follow a period–luminosity relation, but it is about 1 to 2 magnitudes fainter, and it has a shallower slope, as shown in figure 4. The W Virginis stars have periods between $\sim$1 and 30 days, and then they smoothly merge into RV Tauri stars that have light curves with alternating deep and shallow minima, along with more or less periodic behavior that is attributed to low-dimensional chaos. BL Herculis and a few other short-period type II Cepheids with periods of about a day are sometimes considered as a subgroup of the W Virginis stars; they have a bump on the declining part of the light curve about a quarter period after maximum light.

Red giant pulsars

Most red giant branch (RGB) and AGB stars pulsate with periods ranging from about 25 days to over a year (see RED GIANT STARS). The periods are usually somewhat irregular, although a fairly accurate mean period can be derived for most of these stars. In visible wavelengths, the pulsation amplitudes can vary from a few hundredths of a magnitude up to 7 or 8 magnitudes. Objects with extreme amplitudes in the visible appear so for two reasons. First, the Johnson V filter covers the same wavelength range as the most prominent TiO absorption bands, and the strength of these absorption bands increases rapidly with decreasing temperature. Secondly, the star becomes cooler as it becomes fainter, and the energy output shifts towards the infrared where our eyes cannot see. In most cases, the bolometric amplitude is about 1 magnitude. The pulsations are probably driven by partial ionization of H and He, but the dominance of convection in the outer layers makes theoretical pulsation calculations difficult due to pulsation–convection coupling that is difficult to model. These modeling difficulties also contribute to the ongoing debate about whether Mira stars are pulsating in the radial fundamental or first overtone mode. Many variable star classes are known in this part of the H–R diagram. The most famous are the Mira variables, which have visual amplitudes greater than 2.5 magnitudes. Other classes include the semiregular variables (SRa and SRb) and the irregular variables (Lb and Lc); these stars tend to have smaller light curve amplitudes ($\sim$1 magnitude (mag) in the visual) than the Mira stars. Of these, the Lc stars are supergiant stars, and by implication are more massive than the other RGB and AGB variable stars. As the name implies, the semiregular and irregular variables have more erratic light curves than the Mira stars. One of the relatively unexplored frontiers is connecting the pulsations with mass loss. All of the RGB and AGB stars have extended, low-gravity envelopes, and pulsations cause appreciable mass loss during the time an RGB or AGB star spends in this part of the H–R diagram. It also appears that pulsation induces the final episode of mass loss as a star leaves the asymptotic giant branch to become a planetary nebula.

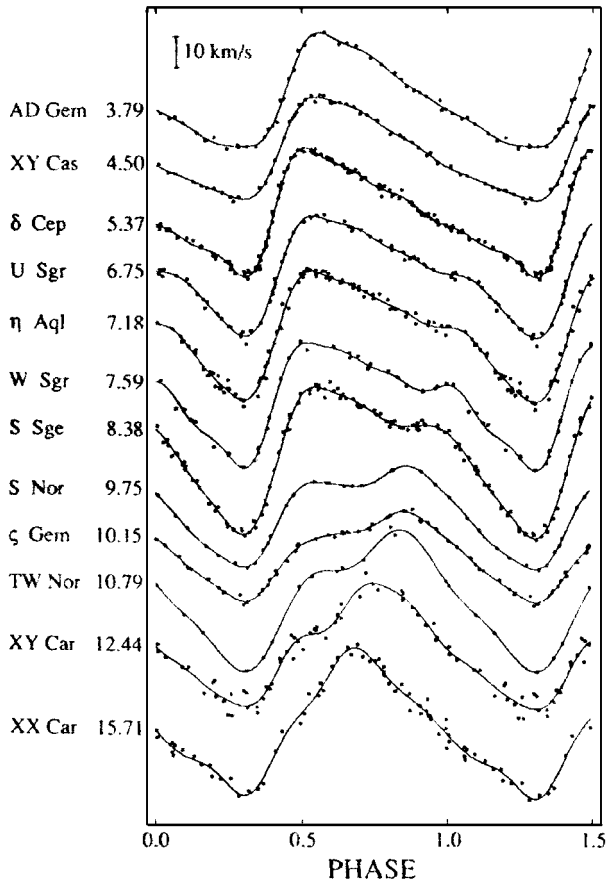

Figure 3. A sample of Cepheid variable star radial velocity curves. The interval between maximum and minimum radial velocity (or brightness in a light curve) is called the amplitude (A); the time interval between successive maxima is the period (Π), and the fractional period between one maximum and the next is called the phase (ϕ). Note the Hertzsprung 'bump' progression between 6 and 15 days.

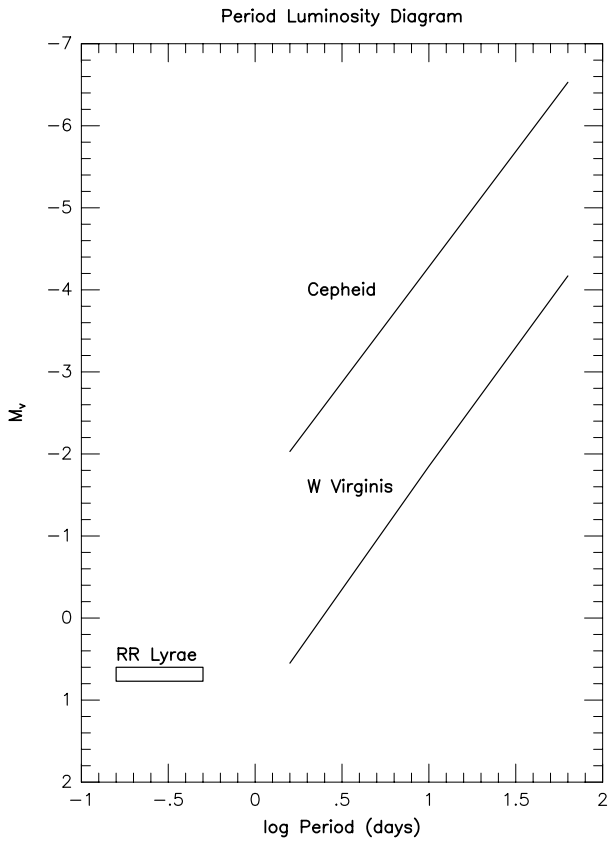

Figure 4. Period–luminosity relations for RR Lyrae stars, 'classical' Cepheids and W Virginis stars.

RR Lyrae stars

RR LYRAE STARS are also radial mode pulsators, but are population II stars that are burning helium into carbon and oxygen in their cores. The typical effective temperature for an RR Lyrae star is about 6500 ± 500 K, and they have a luminosity of about 40 to 50$L_\odot$. The periods of RR Lyrae stars are typically 0.2 to 1.2 days, with amplitudes ranging from a few tenths to about 2 magnitudes. They are frequently called 'cluster variables', because most of the known examples are located in the GLOBULAR CLUSTERS of our galaxy. RR Lyrae stars are bright enough to be visible in nearby galaxies and are used as distance indicators, because they have a relatively well-determined average absolute magnitude. There are subclasses of RR Lyrae stars—called RRa, RRb, RRc and RRd—that are classified according to the shape of their light curves; the RRa stars have asymmetric light curves with steep rises and more gradual declines, RRb stars have light curves with lower amplitudes (about 0.6 mag), but are otherwise similar in appearance to RRa stars, and both classes pulsate in the radial fundamental mode. RRc stars have nearly sinusoidal light curves with amplitudes of about 0.5 mag and are radial first-overtone pulsators. The RRd stars are double-mode stars with both the fundamental and first overtone modes excited. In addition, some RR Lyrae stars show a periodic modulation of the amplitude and shape of their light curves in a quasiperiodic manner called the Blazhko effect; however, this modulation leaves the period of the pulsation mode unchanged, except for possible evolutionary effects. The origin of the Blazhko effect is not understood yet, although magnetic field modulation and nonlinear effects have been proposed.

δ Scuti

Several classes of variable stars lie near the main sequence with spectral classes between early A and early F, with the most obvious distinction being their pulsation periods. The δ Scuti stars are the most numerous and best known of these pulsators. The δ Scuti stars are spectral class A5 to F2 stars that are burning hydrogen either in their cores or in a thick shell surrounding the core; they have masses between 1.6 and 2.6$M_\odot$. They can be monoperiodic or multiperiodic (the record holder has more than 20 known periods), with periods between 0.5 and 6 h. The

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

amplitudes range from the photometric detection limit (<1 millimag) up to about 1 magnitude. The pulsations are a combination of radial and/or non-radial modes; most of the non-radial modes are low-overtone p-modes, although in some cases we may be seeing low-overtone g-modes. Typically, the large-amplitude pulsators are more evolved, slower rotators, and have one or a few (mostly radial) modes present. Lower-amplitude δ Scuti stars are found throughout the instability strip, and many of these stars rotate rapidly, with $v \sin i$ values ranging up to 220 km s^{-1}. A plot of the number of δ Scuti stars versus pulsation amplitude shows a rapid rise towards lower amplitudes down to instrumental detection limits. This suggests that the ~30% of stars in the instability strip that are δ Scuti stars is actually a lower limit, and that many more are waiting to be discovered. Pulsation driving for δ Scuti stars comes mostly from He^+ to He^{2+} ionization, with some driving from H to H^+ and He to He^+ ionization. δ Scuti stars are promising candidates for astroseismology, and several stars have been analysed. The observations require observing runs of a month or more from several sites around the globe to reduce confusion in analysing the period spectra and also to reduce the noise level enough to detect the low-amplitude modes that are present. Because most δ Scuti stars are rapid rotators, rotational splitting effects must be included in theoretical pulsation frequency calculations and in the evolutionary models, which is challenging. So far, only a handful of stars have been analysed, and the analyses to date underscore the need to include the effects of rotation to predict the pulsation frequencies reliably.

δ Scuti pulsations also show up in two classes of metal-poor stars. First, there are the Pop II SX Phoenicis stars, which are large-amplitude radial pulsators. The SX Phoenicis stars tend show up in dense open clusters and globular clusters as BLUE STRAGGLERS, and it is likely that they are binary merger objects. The second type are pulsators within the λ Boötis spectral class; about 50% of these stars are also low-amplitude δ Scuti type pulsators. The existence of pulsations in the λ Boötis stars suggests that the deficiency of some metals in their spectra is a superficial phenomenon and that the driving region is probably not metal or helium depleted. Otherwise, we would not expect to see pulsations because the required partial ionization zone would not be present.

Rapidly oscillating Ap stars

The rapidly oscillating Ap (roAp) stars are A stars with peculiar spectra that show enhancements of metal lines, typically of transition metals and rare-earth elements (see PULSATING AND CHEMICALLY PECULIAR UPPER MAIN SEQUENCE STARS). They pulsate in high-overtone p-modes that have amplitudes of about 1 to 10 millimag, and the periods range from 4 to 15 min. These stars have strong (up to kilogauss) magnetic fields and are slow rotators, with rotation periods ranging from about 2 to 12 days. The combination of a strong magnetic field and slow rotation is the key to explaining the light variations using the *oblique pulsator model*. Here, the light variations are due to a dipole ($\ell = 1$) mode that is aligned with the magnetic field, causing the aspect angle of the light and dark hemisphere to change as the star rotates. The oblique pulsator model is quite successful in explaining the observed pulsation behavior, including the pulsation phase jumping by π radians during a magnetic field reversal. The magnetic fields are sufficiently strong that they influence the nature of the pulsations, and this is something that has yet to be modeled consistently in pulsation calculations. These stars occupy much the same region of the H–R diagram as the δ Scuti stars, but there the similarity ends. The short periods of the pulsations are consistent with pulsation driving due to the κ mechanism in the H/He partial ionization zone, but this requires models with chemically inhomogeneous envelopes to deplete the He^+ ionization zone of enough He to 'quench' the δ Scuti pulsations that would otherwise be present. Understanding the nature of pulsation driving and the structure of the outer layers of roAp stars is an area of active development.

γ Doradus stars

The final class of pulsating stars in the A to F spectral class that we discuss includes the newly discovered γ Doradus variables. The γ Doradus stars lie just coolwards of the δ Scuti instability strip with spectral classes between F0 and F3. They lie on or near the main sequence and have masses near $1.5 M_\odot$. The periods range from about 0.5 to 3.0 days, which is far longer than the radial fundamental mode; the fact that several stars are multiperiodic implies g-mode pulsation rather than a rotating, spotted star. At present, the pulsation driving mechanism is not known, but the likely candidate is the κ, γ mechanism acting in a region enhanced in metal abundances due to diffusion with a temperature of about 200 000 K. Thus, the A to F stars appear to show the full range of possible opacity driving mechanisms, from H/He driving near the surface in roAp stars, 'normal' He^+ driving in the δ Scuti stars, and driving due to iron-peak metals in the γ Doradus stars.

β cephei stars

There are several classes of photometric and spectroscopic pulsating stars of spectral type O and B that are on or just off the main sequence. Of these, the best known are the β Cephei stars, which are B0 to B2 stars of luminosity class III, IV and V that pulsate with periods between 3.5 and 6 hours. Most have V-magnitude ranges below 0.2 mag, radial velocity amplitudes below 50 km s^{-1}, and are relatively slow rotators ($v \sin i \leq 150$ km s^{-1}), although exceptions exist. The pulsations are radial and non-radial p-modes, and are driven by the κ mechanism acting on iron peak elements. Many β Cephei stars are found in young GALACTIC OPEN CLUSTERS, and these observations show that most are core hydrogen burners, along with some in the core contraction and hydrogen shell burning phase of their evolution.

Slowly pulsating B stars

The slowly pulsating B (SPB) stars are mid to late B stars on the main sequence that exhibit low-amplitude light variations (<0.1 mag) with periods ranging from 0.6 to 3 days. They are like the β Cephei stars in that their pulsations are driven by the κ mechanism acting on iron peak elements, but the driving region is located deep enough in the star to drive the longer observed periods, which are g-modes. SPB stars have masses between 2.5 and $6M_{\odot}$, and they are all core hydrogen burning stars. Almost all of these stars are relatively slow rotators with $v \sin i \lesssim 100$ km s^{-1}. Some also show line profile variations, where the shape of the spectral line changes in a periodic manner as different light and dark patches are seen on the rotating star.

Line profile variables

A number of O and B stars show line profile variations due to non-radial pulsations. Two classes of objects have prototype stars; they are ζ Ophiuchi and 53 Persei. Many of these stars are rapid rotators, and the theoretical framework is only just now being constructed for us to interpret their pulsations. Finally, there are the B stars with emission lines in their spectra (BE STARS); a few show line profile variations, and many show photometric variability with periods of about a day. Currently, there is considerable debate on whether the observed light variations are due to pulsation or some other mechanism; we mention the Be stars here for completeness and as a warning that we do not understand their observed behavior yet.

Pulsating white dwarfs

WHITE DWARFS are the remnants of stars with initial masses less than $8M_{\odot}$, and some of them pulsate in well-defined temperature ranges, with typical maximum amplitudes up to 0.3 mag. All of these stars are multiperiodic g-mode pulsators, and several have precise structural and intrinsic properties derived from astroseismological analysis of their pulsation periods. Some of these stars are still contracting appreciably and are classified as pre-white dwarfs (PWDs). The most luminous PWDs are the PLANETARY NEBULA nuclei variables (PNNVs), which are evolving rapidly from thermally pulsing AGB stars to the white dwarf domain. They have typical periods of 1000 to 2000 s. The hottest pulsators are the pulsating PG 1159 (or GW Virginis) STARS, which have temperatures between 80 000 and 160 000 K. Their pulsations are probably driven by partial ionization of C and O. The nature of the pulsation mechanism of the cooler white dwarfs has been a subject of some debate, but evidence is beginning to favor the idea that convection zone modulates the energy flow due to *convective driving*, where the pulsation energy is modulated by adjustments of the convection zone. At about 25 000 K, the convection zone in the helium layer drives pulsations, and here we find the variable DB white dwarfs (called DBV or V777 Herculis stars) (see DB PULSATING STARS). Typical periods range from 400 to 1200 s, and the DB spectral type implies that the atmospheres are pure helium. The coolest pulsating white dwarfs have a DA spectral type and they are called DAV or ZZ Ceti stars. Pulsation driving occurs in the hydrogen layer convection zone; they have temperatures between 11 000 and 12 000 K and periods ranging from 100 to 1200 s. Astroseismology shows that the surface layer of hydrogen for several of the ZZ CETI stars has a mass of about $10^{-4}M_{\star}$.

Other pulsating stars

Space prevents a discussion of all the classes of pulsating stars, but we will mention a few other classes of stars that exist and recommend the reader consult the bibliography for further details. The most luminous pulsators are the Luminous Blue Variables (LBVs), which appear to be massive ($M_{\star} > 20M_{\odot}$) stars that are up to 10^6 times as luminous as the Sun (see HIGH-LUMINOSITY STARS). Possibly related to the LBV stars are the A-type supergiant α Cygni and others like it; they appear to be somewhat less massive and cooler than the typical LBV star. Some evolved low-mass stars show reduced amounts of hydrogen in their atmospheres, and a subset of these stars pulsate. First are the spectacular R CORONA BOREALIS STARS, which have nearly constant maxima interspersed by dramatic dimming episodes. Second are the extreme helium pulsators, sometimes also called hydrogen-deficient (H-deficient) stars. There are also K giant stars that pulsate, although they have not been systematically observed or reviewed. The best known example is Arcturus, and all of these stars have very low amplitudes, requiring high-precision photometry or spectroscopy to detect (see LARGE HOT SUBDWARFS AND EXTREME HORIZONTAL BRANCH STARS). Finally, there are the EC 14026 stars, or pulsating subdwarf B (SdB) stars, which are core helium burning stars with hydrogen-rich envelopes that have too little mass for the star to ascend the AGB.

The advent of astroseismology

In the previous discussion, we alluded to some situations where the study of pulsating stars impacts other fields of astronomy. Each pulsation mode in a star can be thought of as an independent probe of the star's interior, and using this information to determine (or constrain) the interior structure of a star is what the subject of astroseismology is about. The analogous field for the Sun is helioseismology, and this subject is covered by other articles in this encyclopedia (see SOLAR INTERIOR, HELIOSEISMOLOGY: THEORY, HELIOSEISMIC OBSERVATIONS). Even if a star pulsates in only one or two modes, this can reveal the mean density. This is enough that in the case of Cepheids and δ Scuti stars, N Simon suggested in 1982 that enhancing the opacities in the region around 200 000 K would resolve a number of outstanding discrepancies between observation and theory. Two major efforts at recalculating the opacities (the Opacity Project with the OP tables and Lawrence Livermore National Laboratory with the OPAL tables) found the suggested opacity enhancements (see SOLAR INTERIOR: EQUATION OF STATE AND

Dirac House, Temple Back, Bristol, BS1 6BE, UK

OPACITY). This essentially solved the double-mode period ratio problem in Cepheids and the discrepancy between the pulsation and evolutionary masses of Cepheids, and also revealed the driving mechanism for the β Cephei and SPB stars.

More precise determinations of the internal structure are possible if many pulsation modes are observed, and the present record holders (excluding the Sun) are the white dwarfs PG 1159–035 (see the example light curve in figure 5) and GD 358, with over 100 modes present in each star (see STELLAR INTERIORS). Next best are δ Scuti stars, where some have about 20 modes present. Much current theoretical and computational effort is going into developing better evolutionary models for various classes of stars for pulsation analysis. The other areas of intense theoretical effort are as follows: including the effects of rotation self-consistently in interpreting observational photometry and spectroscopy; computing the evolutionary models; and computing the frequency shifts induced by rotation.

Identification of the ℓ, m and n 'quantum numbers' for observed pulsation modes is crucial for unlocking the internal structure of a star via astroseismology. A variety of methods are available for these purposes, although none is applicable for all types of pulsating stars, and each has its strengths and weaknesses. If enough pulsation modes are present (say for some pulsating white dwarfs), one can use the regular pattern of period and/or frequency spacings to determine the mode identification. This is the only method that can, in principle, determine the ℓ value, the overtone number (n), and the azimuthal quantum number (m). Radial modes, p-modes, and g-modes can also leave their signature in the form of line profile variations, changes in the equivalent widths of spectral lines, changes in time-dependent amplitudes as a function of color, and different times of maximum light in different wavelengths. Non-radial pulsations, in particular modes with $\ell = |m|$, will have spectral line profiles that change shape as different parts of the non-radial mode become visible as the star rotates. This techniques works best on the O- and B-star pulsators. The equivalent width method makes use of spectral lines whose equivalent width is very sensitive to temperature. Comparing these changes to changes in the ratio of light curve amplitudes for different color photometric filters allows determinations of the ℓ value, but not n or m. Other similar methods make use of comparisons between the phase of radial velocity curves and light curve intensity ratios in different colors. So far this method has seen the most application and success with δ Scuti stars. These methods do not work for white dwarfs, but in this case, the light curve amplitude increases rapidly with decreasing wavelength and the rate of the amplitude increases is a strong function of ℓ. This method requires time-dependent UV amplitudes, and the few white dwarfs studied so far have $\ell = 1$ or 2. The last method depends on knowing the pulsation period and assuming that it is a radial mode. Assuming radial mode pulsations, one can estimate the *pulsation constant* (Q) via

$$Q = \Pi\sqrt{\bar{\rho}/\bar{\rho}_\odot}$$

where $\bar{\rho}_\odot = 1.41$ g cm^{-3} and $\bar{\rho}$ for variable stars of a given class can usually be estimated with tolerable accuracy because it is a slowly varying function of stellar parameters. The pulsation constant decreases rapidly with increasing overtone number, so it offers an estimate of the overtone number n instead of the ℓ value.

A better understanding of pulsation driving has also led to the prediction of some classes of pulsating stars before they were discovered observationally. The first example was the prediction of the pulsational instability of helium atmosphere white dwarfs by D Winget in 1981, based on understanding that the same mechanism causing the hydrogen atmosphere white dwarfs to pulsate should also apply to the helium atmosphere white dwarfs. The next predicted pulsating star class was the subdwarf B-stars (SdB stars), predicted by S Charpinet 1993.

One class of pulsating stars that has not been found as yet are the solar-like pulsators. After seeing the importance of solar pulsations in determining the Sun's structure, people started trying to find similar pulsations in other stars, with Procyon and α Centauri being two of the favorite targets. To date, none of these searches has produced a verifiable detection, although unconfirmed detections and upper limits abound. Much of the lack of success is due to the extremely low expected amplitudes; for the Sun, the amplitudes are on the order of cm s^{-1} or $\Delta I/I \lesssim 10^{-5}$, which is at least an order of magnitude more sensitive than any search to date.

Expanding on the future

For the future, several trends are starting to appear. The early 1990s saw the advent of searches for massive compact halo objects, and 'massive photometry' is becoming a powerful new technique for relatively unbiased populations of previous and newly discovered variable stars, particularly in the MAGELLANIC CLOUDS. For example, the MACHO project has discovered thousands of new variable stars in the LMC, including RR Lyrae, Cepheid, W Virginis and long-period variables; most of them are new discoveries.

Satellites are also sources of new variable star detections. The HIPPARCOS satellite discovered a large number of SPB stars, yet only a few new β Cephei stars, suggesting that selection effects of previous searches severely undersampled the population of SPB stars. Multilongitude, multisite networks are becoming the tool of choice for observers who wish to disentangle the complicated light curves of multiperiodic stars like the pulsating white dwarfs and δ Scuti stars. The Delta Scuti Network (DSN) and Whole Earth Telescope (WET) are two of the longest running and best-known collaborations, although there are many others, including MUSICOS, which is probably the only multisite network devoted to spectroscopy.

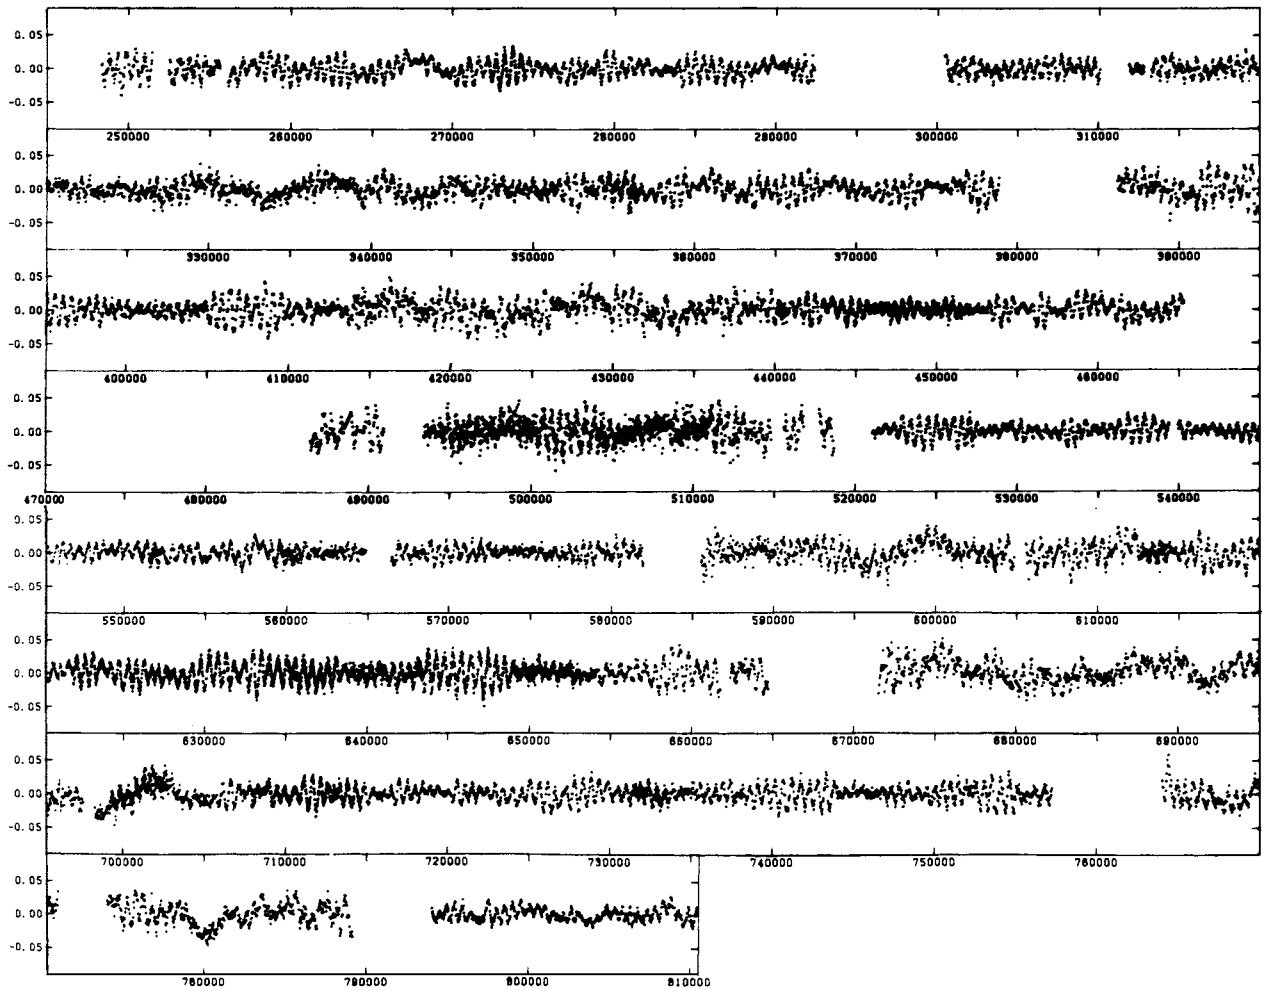

Figure 5. A sample light curve for the multiply periodic pulsating pre-white dwarf PG 1159–035. Note the 'beating' caused mainly by interference between the dominant 516 and 539 s pulsation modes.

Another trend is the appearance of new theoretical and computational tools for understanding the observed pulsations and exploiting the potential of astroseismology. There are three major areas of activity. First, many of the δ Scuti and upper main sequence stars rotate rapidly, which requires the inclusion of rotational physics in the evolution, pulsation and atmosphere models. Second, although many stars are non-radial pulsators, there are at present very few theoretical tools for studying the nonlinear aspects of non-radial pulsations. Besides amplitude variations, many non-radial pulsators also show Fourier transform peaks with frequencies equal to the sum and/or difference of the larger amplitude pulsation modes. These 'combination' peaks are not regarded as real pulsation modes, but they do contain information about the energetics of the driving region, mode selection and nonlinear effects that we are ignoring at present. People are starting to develop theories for understanding this nonlinear behavior, and this should become an area of increasing activity in the near future. Finally, many pulsating stars have convection zones that play at least some role in the driving and damping of pulsations. To date, most theories for convection are either too simplistic, have too many free parameters to be predictive, and/or add enough extra complications that the computer time required for calculations goes up enormously. Add to this the fact that there is no one agreed-upon model, and we have our current situation where convection is either ignored or treated simplistically. The return to pulsational stability at the cool (red) edge of the instability strip for many stars depends on convection/pulsation interactions, as does the existence of pulsations in several classes of stars. While some basic understanding of stellar pulsation can be gained with current simplified models, more effort will be needed here before we can make quantitative predictions about mode selection and mode amplitudes.

Bibliography

The topic of stellar pulsations has a vast literature, so we only provide references to some key papers and books covering the development of the field, along with guides to surveys of recent research. Except where noted, one should assume the material is technical.

Good and readable accounts of variable stars in general that have much material on pulsating stars are:

Hoffmeister C, Richter G and Wenzel W 1985 *Variable Stars* (Berlin: Springer)
Petit M 1987 *Variable Stars* (New York: Wiley)

Good discussions on the early history of the theory and observations of pulsating stars may be found in:

Ledoux P and Walraven T 1958 *Encyclopedia of Physics* ed S Flügge (Berlin: Springer)
Rosseland S 1964 *The Pulsation Theory of Variable Stars* (New York: Dover)

The best general references on stellar pulsation are:

Cox J P 1980 *Theory of Stellar Pulsation* (Princeton, NJ: Princeton University Press)
Gautschy A and Saio H 1995 *Ann. Rev. Astron. Astrophys.* **33** 75
Gautschy A and Saio H 1996 *Ann. Rev. Astron. Astrophys.* **34** 551
Unno W, Osaki Y, Ando H, Saio H and Shibahashi H 1989 *Nonradial Oscillations of Stars* 2nd edn (Tokyo: University of Tokyo Press)

The two most recent conference proceedings devoted to stellar pulsation are:

Bradley P A and Guzik J A (eds) 1998 *A Half-Century of Stellar Pulsation Interpretations: a Tribute to Arthur N Cox* (San Francisco: Astronomical Society of the Pacific)
Stobie R S and Whitelock P A (eds) 1995 *Astrophysical Applications of Stellar Pulsation* (San Francisco: Astronomical Society of the Pacific)

P A Bradley

Stellar Rotation on the Main Sequence

The conservation of ANGULAR MOMENTUM is the one effective counterbalance to the inexorable pull of gravity in the universe, and so everything rotates. Stars acquire their angular momentum when they form, and, indeed, the manner in which nearly all this initial angular momentum is dissipated remains poorly understood, but without substantial angular momentum loss an interstellar cloud could never contract enough to become a star.

Yet stars do form and overcome this problem. When hydrogen fuses to helium in the core, the star is on the main sequence. The rotation rates of all but a few main sequence stars are well below breakup velocity (the speed at which centrifugal force balances gravity at the equator), and rotation therefore is unlikely to fundamentally alter a star's evolution. In those few cases with excessive rotation, the gravity experienced by the star is diminished, and the overall evolution can be very different.

The rotation of a star is usually described by a single number: either $v \sin i$, the equatorial speed of the star projected onto our line of sight, or $P_{\rm rot}$, the rotation period. However, rotation is presumably three dimensional and can vary with latitude on the star (differential rotation) or with radius. On the Sun, there appears to be no change in rotation with radius (as determined from helioseismological studies of the Sun's interior; see SOLAR INTERIOR: ROTATION), but the Sun spins a little faster at its equator than at high latitudes. This DIFFERENTIAL ROTATION does not affect the deep interior, but it is crucial in determining much of the surface phenomenology that makes the Sun so fascinating: spots, plages, active regions, the corona and so on.

Observational technique

The first study of stellar rotation was made by Galileo when he associated the apparent motions of sunspots with the spin of the Sun. Soon after, Scheiner showed that the spots moved at different rates at different latitudes, demonstrating the existence of differential rotation and the fact that the Sun is a fluid.

The study of stellar rotation was systematized by OTTO STRUVE, a spectroscopist who explored many areas of astrophysics. He showed that different line widths in different stars were due to rotation, and he refined the most basic technique for determining rotation: analysis of line breadths in spectra, either by visual comparison or by profile fitting. Early-type main sequence stars (types O, B, A and early F) typically have $v \sin i$ values of 50–400 km s^{-1}. The intrinsic breadth of stellar absorption lines is only about 10–20 km s^{-1}, so the effect of rotation is obvious in early-type stars. Such stars are also intrinsically bright and blue and so were prime targets during the photographic era (see STELLAR ATMOSPHERES: EARLY-TYPE STARS). As a result, most of the data for early-type stars date from that time. This method is calibrated by direct measurement of line widths for a range of rotation rates: $v \sin i$ is then half the full width of the line where it meets the continuum. Once suitable standards are established, a well-trained eye can reliably estimate $v \sin i$ down to about 10 km s^{-1} with an accuracy of 1 km s^{-1}.

As noted, $v \sin i$ is that component of the star's true equatorial rotation rate that is projected onto the line of sight. Such information is entirely adequate for studying the rotation of classes of stars for two reasons. First, the rotation axes of stars are randomly oriented in space. This has been determined by, for example, observing rotation in clusters of stars at different Galactic latitudes and noting that high-latitude clusters have the same distribution of rate as low-latitude clusters. The immediate conclusion from this fact is that stellar rotation does not have its origin in Galactic rotation. The orbital axes of visual binaries have also been shown to be oriented randomly. Second, for a random distribution of axes one is most likely to observe a star nearly equator on (for about 87% of stars the measured $v \sin i$ is at least half of the true equatorial velocity), and stars are very unlikely to be seen pole on. In other words, nature makes it easy. However, the inevitable ambiguity of $\sin i$ makes it impossible to specify the rotation rate of an individual star reliably.

The most massive stars are not as congenial to this method as later spectral types. Many of them have very high rotation rates (300 km s^{-1} or more), making it difficult to define the observed spectrum line. In such cases there can also be important physical effects such as gravity darkening that influence spectrum formation in the first place. Also, the dearth of sharp-lined O stars strongly suggests the presence of turbulent broadening, but the precise extent of that turbulence is not well understood. For most massive stars, rotation is so dominant that this uncertainty in the zero point is not critical.

This same technique of measuring line broadening was applied to stars as cool as the Sun but without success: they were all rotating too slowly to be resolved on moderate-resolution spectra (see also STELLAR ATMOSPHERES: COOL STARS). The slow rotation of late-type stars (late F, G, K and M) is intimately tied to the presence of convective envelopes on those stars, as discussed below. More recently it has been possible to determine $v \sin i$ values down to about 2 km s^{-1} by obtaining high-resolution ($R \approx 100\,000$), high signal-to-noise (200 or more) spectra and by then applying careful modeling of the entire line profile. Fitting of the Fourier transform of the profile also helps to deconvolve rotation from other broadening mechanisms of comparable magnitude. The uncertainties of this procedure are relatively large (about 1 km s^{-1}) when $v \sin i$ is small, but it allows the determination of rotation in slowly rotating solar-type stars, for which no other information exists.

As discussed below, the fundamental nature of late-type stars leads to their exhibiting solar-like phenomena such as surface spots. These spots can be significant enough to lead to detectable variations in the light of a star from which the rotation period, $P_{\rm rot}$, can be determined. This is essentially the inverse of the angular velocity, Ω. Rotation periods are independent of aspect, and so it

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

is now possible to determine accurately true rotational distributions for a sample of late-type stars. Changes in the observed $P_{\rm rot}$ or multiple periods in one dataset have been interpreted as evidence for differential rotation. Differential rotation is a key ingredient of models for generating magnetic fields in late-type stars and so these observations are valuable, but information is available for only a few stars, and those are not old, quiet ones like the Sun. An attempt has been made to detect differential rotation in some A stars through very careful analysis of the line profiles, but none was seen. It has also been possible to measure rotation periods for some early-type stars because they can also have magnetic fields that lead to inhomogeneous surfaces, hence variations. These have been especially important for some of the Ap/Am stars.

More details on technique may be found in Gray's excellent text on stellar atmospheres (Gray 1992).

Sources of observations

Because the rotation of early-type stars was well studied photographically, most of the observations for those stars were compiled into comprehensive catalogs long ago. The original catalogs are in fairly obscure observatory publications, but all of these data and more can now be accessed at NASA's Astronomical Data Center (adc.gsfc.nasa.gov). For individual stars, the best source is SIMBAD (simbad.u-strasbg.fr/Simbad).

As with any database, discretion should be used in interpreting data, as not all are of the same quality. In some instances significant misconceptions by some observers have led to large systematic errors that propagate into the catalogs: see Soderblom *et al* (1989) for an example.

General remarks on rotation

Each type of main sequence star has rotational characteristics that set it apart from other types, but there is a natural break in the mid-F spectral type range. For early spectral types (O, B, A and early F), energy is carried to the surface predominantly by radiative processes. For the late-type stars (late F, G, K and M), energy transport in the outer layers is by convection. The presence of a convective envelope and its interaction with the rotation are fundamental to the behavior of late-type stars, as will be discussed below.

Two basic facts apply to rotation in stars. First, the rotation axes of stars are randomly oriented. As noted above, this means that stellar rotation does not have its origins in Galactic rotation, for if it did then rotation axes would tend to be aligned with the Galaxy's rotation. The second basic fact is that a mean relation appears to hold for the specific angular momentum of a star at the time of formation (its angular momentum per unit mass) and the star's mass, first shown by Kraft:

$$\langle I/M \rangle \propto M^{-1.1}.$$

where I is the angular momentum and M is the stellar mass. This relationship (Kawaler 1987) can easily be derived by assuming that all stars form from a medium of uniform density, a condition that is surely not true in nature. Also, the need to dissipate most of a star's initial angular momentum weakens the tie between initial conditions and later behavior on the main sequence, and the underlying reason for the above relation is not obvious. The Kraft relation is at best a statistical one that predicts a typical amount of angular momentum for a star of a given mass. There are, for example, well-studied binary systems with components of nearly identical mass yet substantially different $v \sin i$ that demonstrate that initial conditions are important too.

The early-type stars: O, B, A and early F

The most massive stars (O and B types) sometimes show evidence of NON-RADIAL STELLAR PULSATIONS and strong winds, as well as abundance anomalies that may be driven by internal mixing. All these effects are related to rotation and complicate the determination and interpretation of rotation, and rotation rates can be high enough to influence a star's evolution. Intermediate-mass stars (types A and early F) can have dramatic abundance anomalies and other effects that are related to diffusion in the surface layers, which in turn is affected by rotation. The presence of significant rotation in these stars in itself complicates studies that depend on measuring weak lines (to determine abundances) or on resolving components of absorption lines (to measure magnetic field strengths). Thus phenomena can take place on rapid rotators that cannot be directly observed.

The distribution of $v \sin i$ for the O stars, for example, has two peaks, one centered at about 100 km s^{-1} and the other at 300 km s^{-1}, both about 100 km s^{-1} wide. The highest $v \sin i$ values are near 400 km s^{-1}. The 300 km s^{-1} peak is seen only among the main sequence O stars, and it matches the distribution seen in Be stars, while the 100 km s^{-1} peak is seen in all luminosity classes among the O stars: main sequence, giants and supergiants. Significant turbulence (at about the 20 km s^{-1} level) is present in O stars as well, and this accounts for the absence of stars with sharp-lined spectra. The presence of strong radiation-driven winds in O stars means that significant mass loss is present, and this implies a trend of rotation rate with age while on the main sequence.

Rotation can play a key role in the evolution of very massive stars (10–40$M_\odot$). First, rapid rotation can affect the stellar equilibrium, reducing the central pressure and temperature, leading to lower luminosity. The maximum luminosity decrease is ∼3%. Second, rapid rotation can alter the shape of the atmosphere of the star, creating local differences in temperature and pressure. The effects depend on orientation and tend to make a star look cooler. The most important effect of rapid rotation, however, is its influence on mixing of chemical elements and on angular momentum transport in the STELLAR INTERIOR. Rotation especially influences turbulent diffusion. Higher rotation leads to more efficient turbulent diffusion, and that makes a star have about double the luminosity it would have

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

in the absence of the diffusion. Also, rotationally induced mixing has been used to explain several features of massive star evolution, namely the N and He enrichment of O stars, and the lack of a gap (predicted by models) between main sequence and post-main-sequence stars in the observed H–R diagram.

For B stars, the typical rotation rate is about 140 km s^{-1} for all spectral subclasses, somewhat greater than for the more-massive O stars. A comparison of rotation in B giants with B dwarfs shows that early B stars do not rotate as solid bodies and that differential rotation is important. An important subtype among the B stars is the Be stars (B stars with emission lines), which constitute about 15–20% of B stars. Be stars rotate at higher rates than non-Be stars, with an average equatorial velocity (corrected for $\sin i$) of 265 km s^{-1} and with a distribution of velocities that is not skewed. In other words, the distribution of $v \sin i$ for Be stars is Gaussian, not the Maxwell–Boltzmann function expected for a random distribution of rotation axes. Note that the breakup velocity for Be stars is about 500–550 km s^{-1}, so they are comfortably below that level. The winds seen in Be stars are influenced by the rotation, being slow and dense in the equatorial regions and fast and tenuous at the poles; see BE STARS.

Most O and B stars are found in star-forming regions because they are so young. The distributions of rotation for these various clusters of stars do not differ significantly from one another, given sample sizes. There are real and significant star-to-star differences in angular momenta at a given mass, but the distributions of angular momenta seem to be independent of initial conditions to a large degree. There are suggestions that metallicity plays a role in how angular momentum is distributed within clusters, but not yet enough information to form a clear picture.

Most A and early-F stars have moderate rotation rates (50–100 km s^{-1}) that are consistent with the Kraft relation above, but among the A stars are found objects with peculiar chemical abundances, and these peculiarities are closely related to rotation. The Am, or metallic-line A, stars show weak Ca II and/or Sc II features, but enhanced lines of heavy elements. Many are found in BINARY SYSTEMS, and temperatures range from 7000 to 10 000 K. The Ap, or magnetic A, stars show enhanced lines of elements such as Si, Cr, Eu and Sr, few are in binaries and temperatures range from about 8000 to 15 000 K. The HgMn stars have enhanced Hg and Mn lines and temperatures from 10 000 to 15 000 K.

All of these types have rotation rates well below average for A stars. The average $v \sin i$ for Am and Ap stars is about 40 km s^{-1}, a factor of 3–4 lower than normal stars of the same colors. Several arguments indicate that these low $v \sin i$ values are not due to these stars being rapid rotators seen pole on. The HgMn stars rotate especially slowly: $\leq$20 km s^{-1} in almost all cases. Very few chemically peculiar stars have $v \sin i > 100$ km s^{-1}. Thus a low rotation rate appears to be a necessary condition for the Ap, Am or HgMn phenomenon to arise, but that does not explain why these stars have low rotation rates in the first place. Rotation rates for these peculiar stars decline with age, suggesting that angular momentum loss enabled through a magnetic field (like the late-type stars discussed next) or the presence of a close companion plays a key role. However, the age relationship does not appear to hold for the HgMn stars, leaving their origin uncertain. One argument is that the HgMn stars, being cooler, spend enough time losing angular momentum in the pre-main-sequence phase to achieve the needed low rotation rates. The apparent relation between rotation and age for some of these peculiar stars may be just that—apparent—and the true origins are not fully understood. Note that the inverse statement about rotation and peculiar stars also holds: there are very few, if any, normal A stars that rotate slowly.

The late-type stars: late F, G, K and M

Rotation is a key determinant of much of the phenomena we see on late-type stars because these stars possess convective envelopes that interact strongly with the rotation. The paradigm for understanding this behavior is drawn from what we see up close on the Sun: rotation and convection interact in the outer layers to produce complex circulation patterns in the ionized stellar material. Differential rotation is especially important in this mechanism—the dynamo mechanism (see DYNAMOS: SOLAR AND STELLAR)—that can regenerate a seed magnetic field. The magnetic field, in turn, can grip an ionized stellar wind well beyond the star's surface, forcing angular momentum loss, a process we witness on the Sun. Thus the Sun by its nature loses angular momentum steadily, and, by analogy, other stars with convective envelopes and winds do likewise. We are confident that all late-type stars possess convective envelopes from basic physical considerations. We still know little about winds in stars, however, except in cases where they are very strong, and so we assume that other late-type stars have some sort of wind similar to the Sun's.

One consequence of this paradigm is that two stars formed at the same time but with different rotation rates will tend toward the same rotation rate with time because the more rapidly rotating star generates a stronger magnetic field and so loses angular momentum faster than its slowly rotating sibling. Young stars tend to rotate rapidly because they have not yet had time to lose much angular momentum, while old stars rotate slowly.

The magnetic fields of late-type stars give rise to their rich phenomenology, collectively described as activity. This activity, in turn, can help us study the rotation. Surface inhomogeneities (i.e. spots) can be large enough to produce observable variations in the light of the star and from these the rotation period can be inferred. In general only the young, active stars have measurable rotation periods, although it should be possible to measure the same effect in old stars with observations of sufficient quality since space observations of the Sun reveal its rotation. Careful long-term observations have yielded changes in $P_{\rm rot}$ that indicate the presence of differential

rotation on other stars. The strength of activity in whatever form it is observed (Ca II H and K emission, Hα, x-rays, etc) is strongly correlated with the rotation for late-type stars, so that rapidly rotating stars are always active stars because of the strong magnetic fields generated, while slowly rotating stars are inactive. The rotation–activity relations have different slopes for different masses, so that lower-mass stars produce more activity for a given rotation rate. For reference in what follows, the Sun is 4.6 Gyr old and rotates with a period of about 27 days and an equatorial velocity of 1.8 km s^{-1}.

Young stars are studied by observing them in STAR CLUSTERS, both because most zero-age main sequence (ZAMS) stars are in clusters and because clusters provide good-sized samples of stars of known age. The late-type members of clusters are well cataloged only for the few nearest of the clusters (e.g. the Pleiades, Hyades, α Persei, Praesepe, M34, M67), and so we assume that any one of these clusters provides a representative view of any ensemble of stars at that cluster's age.

The best-studied ZAMS cluster is the Pleiades, at an age of 100 Myr, and the Pleiades tells a very interesting story. The Pleiades contains stars with $P_{\rm rot} = 1/4$ day, or 100 times the solar rate. The fastest-rotating G dwarfs found in the field rotate at about 10 times the solar rate, so these Pleiades stars are extraordinary. These ultrafast rotators (stars with $v \sin i \geq 20$ km s^{-1}) constitute about 20% of the G and K dwarfs in the Pleiades, the remaining 80% typically having $v \sin i$ values below 10 km s^{-1}. Thus the distribution of rotation for these ZAMS stars is bimodal, with the dominant fraction being stars that rotate relatively slowly. Observations of the α Persei cluster (age 50 Myr), while not as complete, confirm that the Pleiades is typical for its age. By contrast, there is very little spread in rotation for G dwarfs in the Hyades (age 600 Myr). Rotation periods are known for many Hyades stars, and the intrinsic spread in rotation about a mean relation is only about 10%. Moreover, there is a strong mass dependence to the rotation seen in Hyades stars, with a sharp decline in going from the late-F stars into the early-G dwarfs, whereas Pleiades stars in the same range show little mass dependence. These clusters tell us that, in the first billion years after reaching the ZAMS, solar-type stars can lose a lot of angular momentum and while doing so a strong mass dependence to the rotation is introduced and at the same time there is a dramatic convergence in the rotation rates. The spread in rotation in the Pleiades at any one mass is at least a factor of 20, versus the 10% seen in the Hyades.

The details of this convergence are still not clear. The fact that it happens so quickly and that such a huge spread exists on the ZAMS has led to the suggestion that the convective envelope of a solar-type star can decouple from its radiative core. This means that we see the less-massive envelope spin down quickly, with more gradual replenishment with angular momentum from the core later. This decoupling model can also help to explain the strong mass dependence seen since the ratio of core to envelope is very sensitive to the star's mass. However, it is not strictly necessary to invoke core–envelope decoupling to explain the observations, and so it is not yet possible to be sure whether that is what is going on.

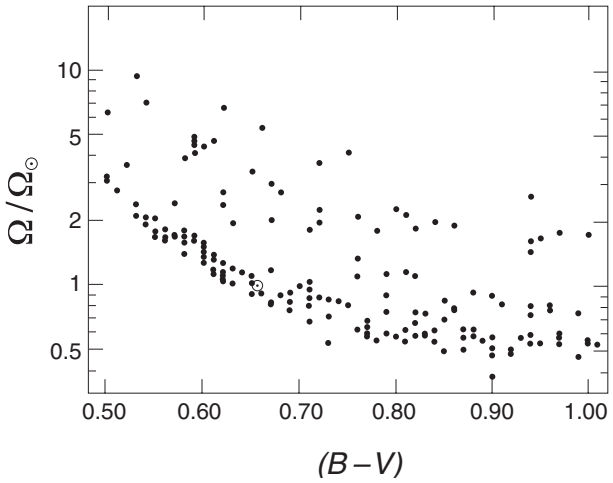

Figure 1. Rotation among solar-type stars. This diagram shows estimated rotation rates for stars like the Sun. A $B - V$ color of 0.50 corresponds to a spectral type of about F7 V and a mass of about $1.2M_\odot$, while $B - V = 1.00$ corresponds to K2 V and $0.7M_\odot$. The rotation rates were computed from measures of activity in the Ca II H and K lines, using a rotation–activity relation calibrated on stars of known rotation periods. The rapidly rotating stars at a given color are the young ones which gradually lose angular momentum to evolve into the slowly rotating stars. The Sun is shown at $B - V = 0.656$. Note that the Sun has a very typical rotation rate for an old star of its mass and that there is a range in rotation of about a factor of 5 at any mass.

Figure 1 shows the distribution of rotation rates from about $1.2M_\odot$ down to about $0.7M_\odot$. Note that the Sun has a very typical rotation rate for an old star of its mass (color). The distribution flattens for $B - V > 0.8$, in part because these low-mass stars have main sequence lifetimes that exceed the age of the Galactic disk, meaning that we cannot yet know how slowly the oldest of them will rotate. The upper bound also flattens for these low masses, which has been interpreted as indicating that the timescale for angular momentum loss becomes longer for lower-mass stars. The distribution is independent of mass, indicating that over this mass range stars all behave similarly.

In going to the lowest main sequence masses rotation becomes increasingly difficult to study. The small radii mean that $v \sin i$ values tend to be small, and these stars are intrinsically faint. A survey of rotation in M dwarfs found only 25% to rotate above the detection limit of 2 km s^{-1}. However, several stars were found with large $v \sin i$ values (30–50 km s^{-1}), all of which were later than M3.5. This is consistent with the timescale for spindown increasing with decreasing stellar mass.

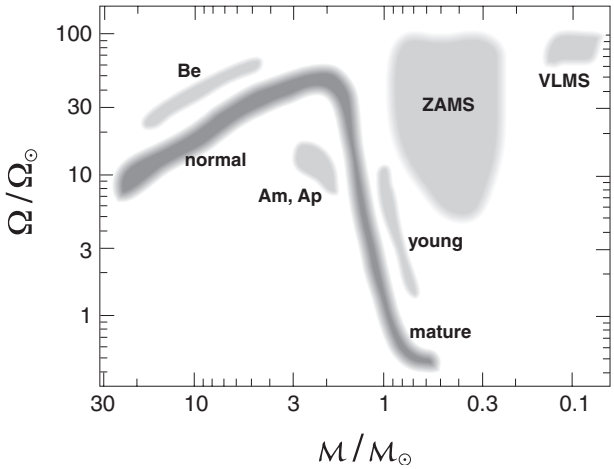

Figure 2. Schematic diagram of rotation in main sequence stars. This figure was computed from characteristic $v \sin i$ values as a function of spectral type, with masses and radii assumed for those spectral types based on model computations. What is shown is the surface angular velocity in proportion to the Sun's, and the values are meant to be indicative of the broad trends. Normal main sequence stars follow the broad, dark line, although little is known for stars below about $0.5M_\odot$. The Be stars rotate at about twice the rate of normal stars in the mass range indicated. Below $\sim 1M_\odot$, the locus of young stars is taken from figure 1, and the ZAMS region shows rotation rates for stars up to ~100 Myr in age. The 'VLMS' region is for very low-mass stars, although no comprehensive information exists for this mass range.

Very low-mass stars: the bottom of the main sequence and brown dwarfs

Only a handful of objects are known with masses at the substellar limit and below. These are all very faint, and, because they are inherently small objects, we expect very low $v \sin i$ values. Thus very little information is now available, yet it is surprising: high-resolution spectroscopy has shown significant rotation in all cases ($v \sin i \approx$ 10–20 km s^{-1}). The objects so far studied tend to be young (because young brown dwarfs are brighter than old ones), but the angular velocities that correspond to these $v \sin i$ values are comparable with the very fastest rotators at, say, $1M_\odot$. More observations are needed to provide a fuller context for interpretation, but the explanation for these high rotation rates probably lies in what defines these very low-mass objects, namely their being fully convective objects.

Summary

Figure 2 summarizes our knowledge of rotation in main sequence stars. The ordinate is the surface angular velocity relative to the Sun's. This declines for the highest-mass stars because such stars are less centrally condensed and so have large moments of inertia leading to large total angular momenta. The Be stars rotate at about twice the rate of normal main sequence stars in the mass range indicated, while Am and Ap stars rotate well below normal A stars. The ZAMS region is broad in both mass and rotation rate because stars at and below $1M_\odot$ reach the ZAMS with widely varying rotation rates. The very low-mass stars are shown, but no comprehensive information exists on rotation in general below $\sim 0.5M_\odot$.

Stephan's Quintet (NGC 7317, 7318A, 7318B, 7319, 7320)

A group of five galaxies in the constellation Pegasus, position RA $22^{h}\ 24^{m}$, dec. $+33^{\circ}\ 42'$. Four appear to be gravitationally interacting, and show similar redshifts. The fifth, NGC 7320, has a much lower redshift and is thus a foreground object not associated with the others. The group was discovered by Édouard Stephan in 1876.

Steward Observatory

The Steward Observatory (SO), created in 1916, is the research arm of the Department of Astronomy of the University of Arizona (UA). Its headquarters are in Tucson, Arizona, on the university campus. Its observational facilities are on Mount Graham (10 m Heinrich Hertz SMT; 1.8 m VATT and the Large Binocular Telescope (LBT) with twin 8.4 m mirrors), Mount Hopkins (6.5 m MMT), Kitt Peak (2.3 m Bok) and the Catalina Mountains (2 $\times$ 1.5 m) in Arizona, and on Las Campanas, Chile (Magellan Project; 2 $\times$ 6.5 m). The LBT, Magellan, MMT, SMT and VATT are all collaborative projects. The SO components of these facilities are used by scientists and students at the UA, Arizona State University and Northern Arizona University.

SO is also involved in space astronomy research, currently including HST, ISO and SIRTF. It is participating in development programs for NGST and TPF of the NASA Origins program. SO also operates the Mirror Laboratory, located under Arizona stadium.

SO research programs focus on optical, infrared and submillimeter astronomy, on theoretical astrophysics, and on astronomical instrumentation. Major areas of current activity include: cosmology; the intergalactic medium; quasars and active galactic nuclei; dynamics, formation and evolution of galaxies; star formation in galaxies, including starburst galaxies; star formation and the interstellar medium; supernovae; degenerate stars; cataclysmic variables; brown dwarfs; and extra-solar planets.

SO has 25 teaching staff, about 25 further research scientists and a total staff of around 250. SO is supported by State of Arizona funding and by research grants and contracts.

Stokes, George Gabriel (1819–1903)

Born in Skreen, County Sligo, Ireland, became Lucasian Professor at Cambridge, best known for his work on hydrodynamics and *Stokes' law* of viscosity. In 1854 he explained the Fraunhofer lines in the solar spectrum as being caused by atoms in the outer layers of the Sun absorbing certain wavelengths, but when KIRCHHOFF later published the same explanation Stokes yielded priority to his more complete account.

Stony Meteorite

A meteorite having a composition primarily of silicates, with only a small (typically 5%) metal content, mostly nickel–iron. Stony meteorites are also referred to simply as *stones*; an obsolete name is *aerolite*. Stones are by far the commonest type of meteorite, accounting for nearly 93% of all known specimens. Their dark fusion crust (where the outer layers have been partially melted by frictional heating during their plunge through the Earth's atmosphere, then resolidified) gives them a resemblance to terrestrial rocks. There are two main classes of stony meteorite: *chondrites* (96% of all stones) and *achondrites* (4%). Chondrites consist of an agglomeration of millimeter-sized *chondrules*, particles believed to represent primordial material that condensed from the solar nebula. The rarer achondrites, as the name implies, lack chondrules, implying that they are fragments of a parent body that has undergone differentiation.

See also: achondrite, carbonaceous chondrite, chondrites.

Stony-iron Meteorite

A meteorite composed of roughly equal proportions of silicate (stony) material and metals (mostly nickel–iron); formerly called a *siderolite*. Stony-irons are the least common of the three main types of meteorite, accounting for less than 1% of all known specimens. The great majority of them fall into either of two main classes: the *pallasites* and the *meso-siderites*. Pallasites consist of a matrix of nickel–iron, the gaps in which are filled with olivine (magnesium–iron silicates), and are inferred to have formed near the core/mantle boundary of a differentiated body. Meso-siderites resemble breccias: they consist of fragments of eucrite and howardite (varieties of achondritic material) mixed with nickel–iron, and are thought to have been produced by impacts on the surfaces of planetary bodies. The largest known single fragment at 1.4 tonnes is the Huckitta (Australia, 1924) meteorite, which is a pallasite. The fragments of the Brenham (Kansas, 1882) meteorite, also a pallasite, that were collected had a total mass of 4.3 tonnes.

Strömgren, Bengt (1908–87)

Danish astronomer, son of a former director of the Copenhagen University Observatory, succeeded his father, but was also director of Yerkes and McDonald Observatories. Strömgren calculated what happened when a hot star emitted ultraviolet into the gas clouds around it, ionizing the hydrogen in a region now known as a *Strömgren sphere*, or the H II region. He created the *Strömgren photometric system* measuring the brightness of stars in defined spectral bands as a quantitative counterpart to the Morgan–Keenan spectroscopic classifications system. With it he determined the sizes, luminosities, etc of the stars.

String Theory/Superstring Theory

A theory of fundamental particles and forces in which the basic entity is an exceedingly short one-dimensional structure (a 'string') rather than a point-like particle. These strings are envisaged as being about 10^{-36} m in length, different modes of vibration of the strings corresponding to different types of particle with different energies and masses. When the ideas of supersymmetry are applied to string theory, the outcome is superstring theory. Superstring theory requires a ten-dimensional spacetime, all but four of these dimensions (length, breadth, height and time) being hidden in the present-day universe. Superstring theory is one of the prime candidates for a 'theory of everything', which embraces all of the forces and particles of nature.

Structure and Evolution of the Sun and Stars, 1800–1955

Evolution by contraction

The idea that stars formed through gravitational contraction of luminous fluids was put on an observational basis by William Herschel (see HERSCHEL FAMILY), who worked very much in the spirit of late eighteenth century naturalism that began to ask questions about the origin and growth of systems. Whereas Kant, Laplace, Buffon and Hutton tended to focus on the origin of the solar system and the earth, Herschel considered stars and stellar systems, a 'natural history of the heavens'. Observing some 2500 NEBULAE, by 1811 he published a classification that described a continuous sequence: diffuse patches condensed and circularized into distinct nebulosities with stellar centers, and eventually into true stars. In Herschel's cosmology, nebular fluids were active and self-luminous.

Aside from the question of the origin of nebular light, stars were believed to shine because they were hot and so naturally questions were raised about the source of that heat, and its maintenance. By the middle of the nineteenth century, lingering speculation about the permanency of the stars was put to rest by one of the consequences of the rise of thermodynamics: the law of energy conservation. The gravitational potential of a fluid mass was itself a source of mechanical energy that was converted into light and heat as the mass contracted. J J Waterston, J R Mayer, William Thomson (Lord Kelvin) and Hermann von Helmholtz all applied this concept to the origin and maintenance of solar heat, and showed that it provided an abundant source of energy greater than any other. Though inadequate to sustain the Sun's output over time scales demanded by geology and biology, gravitational contraction provided the conceptual framework within which astronomers thought about the origin and lives of stars for most of the following century. The term 'STELLAR EVOLUTION' came to describe this process of change from an indefinite to definite form, in the spirit of Herbert Spencer's *First Principles*, although the term 'evolution' itself had been applied to celestial processes as early as the late 1840s by J P Nichol.

During the latter half of the nineteenth century, astronomers accepted the Kelvin–Helmholtz theory of gravitational contraction only in its generality as the source of the Sun's heat, finding the 1870 speculative solar model developed by Washington patent clerk J Homer Lane—based upon thermodynamics, the gas laws, and a theory of convective equilibrium derived from Espy—to be a 'remarkable fact' that might have applicability, depending upon the state of the Sun's constitution. In the 1870s and 1880s, Lane's ideas were developed and refined independently by August Ritter, a professor in Aachen, into a theory of stellar evolution that described how the temperature in a glowing globe of gas varied with radius from the center to the surface of the star. Ritter's mathematical treatment envisioned stars beginning their lives as vastly extended low-temperature gas spheres which heated upon contraction into bright blue and white stars to the point where they became too dense to maintain the perfect gas state. From there on, subsequent gravitational contraction was accompanied by a general cooling of the sphere to the point of extinction. Ritter published some 18 papers in 6 years to produce a comprehensive study of the nature of stars. His work remained obscure, however, until revived by Thomson and others in the 1890s.

In 1888, admitting 'no certain knowledge' about the Sun's structure, solar specialist C A Young felt the Sun had to be gaseous, because of its low mean density, following somehow the laws of Boyle, Dalton and Gay-Lussac. By the end of the century, the source of the Sun's heat remained gravitational, which was not a problem for astronomers, though geologists and biologists found it seriously deficient.

Late nineteenth century scenarios

Ritter's theory of stellar evolution was superficially similar to one created by the astronomical spectroscopist NORMAN LOCKYER at about the same time, and called by him the 'meteoritic hypothesis'. Influenced by the coincidence of a NOVA in the constellation of Corona Borealis in May 1866, the first to be studied spectroscopically, and by a spectacular display of (the now called Leonid) meteors in November, Lockyer sought out a connection between the two, ultimately seeing meteors as a primary mechanical agent of change in stellar evolution. Instead of a mathematical theory of convection, however, Lockyer, the founder and editor of *Nature*, relied upon what he believed was an empirical correlation between spectral features seen in vaporized laboratory samples of meteorites and other substances, and the spectra of nebulae and stars. From his experiments, Lockyer concluded in the 1870s that heat could break down atoms and molecules into more fundamental 'basic' components, and he used this as an explanatory framework to interpret the differences seen in the spectra of the Sun and stars as due to differences in temperature. By the 1880s, he had also concluded that nebulae and nebulous stars exhibited spectra indicating they were composed of incandescent swarms of colliding and vaporizing meteoritic material, and from this constructed a life history for stars which began with nebulous meteoritic swarms, condensed and heated from red to being yellow, blue and white stars as the meteoritic material was consumed, and, having consumed all meteoritic fuel, finally cooled back to dull red stars and to extinction. Lockyer presented his theory in what has come to be known as his temperature arch (figure 1).

Ritter's, and especially Lockyer's, scenario of a double-value temperature history for stars ran against conventional views of the direct descent of hot stars from nebulae, and their subsequent cooling to extinction. H C VOGEL and WILLIAM HUGGINS championed the dominant view, using as evidence the linear sequence of stellar spectra of four major classes which were eventually refined to seven classes by the vast spectroscopic classification project at

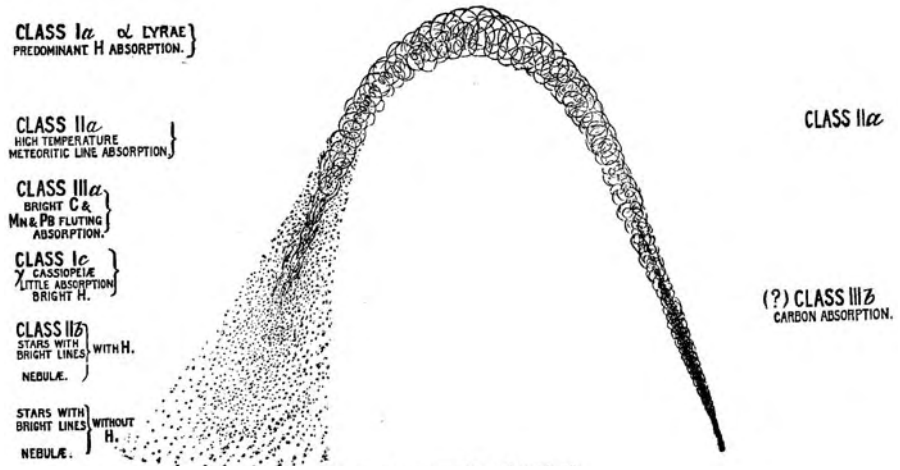

Figure 1. Lockyer's provisional temperature arch. (Figure 67, from Lockyer–1890 *The Meteoritic Hypothesis* (London: Macmillan) p 375.)

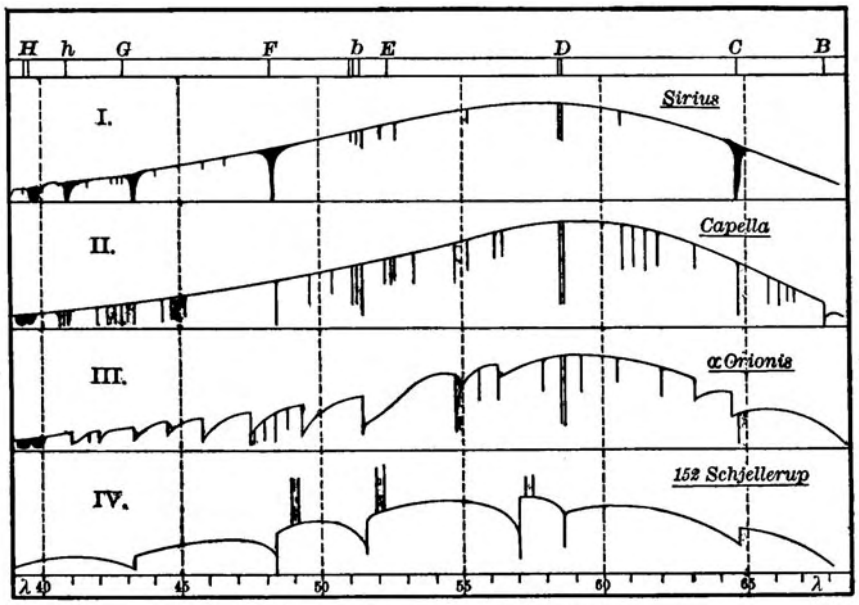

Figure 2. A Secchi's linear sequence of spectra, from blue to red showing the growth of lines. Secchi's and Vogel's similar classifications represented the dominant view of a linear cooling history for stars. (Figure 223, from Young C A 1898 *General Astronomy* revised edn (Boston: Ginn) p 532.)

Harvard in the 1890s (figure 2). Although presented as an empirical classification originally based upon the strengths of the H and K lines of calcium and on the Balmer series of hydrogen, the Harvard system (O, B, A, F, G, K, M) was also a continuous progression of color from white to red. The strengths of the hydrogen lines peaked at Harvard spectral type A, however, because the alphabetical lettering sequence was altered in the 1890s to place stars whose spectra most closely resembled nebulae at the head of the series (O and B). This was clearly an evolutionary consideration.

Huggins and Lockyer engaged in many disputes over their work, and none was as hot as that of stellar evolution. Privately, however, Huggins claimed that he was not against the idea of a double-valued temperature arch, only that he wanted it to be based upon criteria other than those Lockyer was promoting. In 1898, he privately admitted to colleagues that something like a temperature arch based on Lane's law would surely be found someday, but not based upon Lockyer's criteria.

At the turn of the century, then, two different scenarios for the course of stellar evolution were at play. One argued (Lockyer, Ritter) that two classes of red stars (types III and IV on Vogel's system) were widely different in age, and the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

other (Huggins, Vogel) that they were not. Astronomers generally accepted the latter view of the descent of blue stars from nebulae because there was dynamical evidence supporting it. J C KAPTEYN'S detection of two star streams implied that different groups of stars had different origins, and hence that studies of stellar development could somehow be informed by kinematical studies. Correlating the dynamical behavior of groups of stars to evolutionary models was an interest shared by Lick Observatory's W W CAMPBELL, who had already put much of his telescope time and manpower to the task of determining RADIAL VELOCITIES. Less interested in star streaming than in data gathering, Campbell knew that the observed proper motion of a star was statistically an inverse function of its distance, while its radial velocity was independent of distance, and therefore he was on top of one of the most powerful distance-independent techniques for understanding the origins of stars. Starting in 1901, Campbell searched for correlations between kinematics and spectrum class, and by 1910 had found the same increase in velocity with Harvard spectral type that Kapteyn had found. Although a minor priority dispute ensued between the two, the correlation of velocity with age seemed to be an established fact. Since the correlation was linear, this lent strong support to linear descent theories.

Stellar evolution as an agenda

The evolution of the stars, linked closely to the 'sidereal problem', the history of the form and nature of the sidereal universe, both astronomers and astrophysicists claimed at the turn of the century, were driving forces propelling their industry. GEORGE ELLERY HALE cited the problem as a rationalization to build his observatories, and Kapteyn capitalized on it to cement their relationship as Hale turned to the Dutch astronomer to help him define much of the stellar astronomy program at his newly opened observatory atop Mount Wilson. As Hale told Kapteyn in 1907, 'many results obtained in the course of your investigations will be indispensable, if we are to draw any joint conclusions regarding stellar development'. (Hale to Kapteyn, 14 March 1907, Hale Papers, California Institute of Technology, hereinafter 'Hale P'.).

Hale long knew that the pursuit of the deepest problems in astrophysics, specifically the origins and evolution of the Sun and stars, required many talents. On the occasion of thinking through funding priorities for American astronomy in 1906, Hale told SIMON NEWCOMB that astronomers were too specialized and had to be encouraged to move away from 'the details and the merely technical elements of investigation'. (Hale to Newcomb, 21 March 1906, Hale P.) By 1908, Hale justified his research program at his third observatory, the new Mount Wilson Solar Observatory, in terms of stellar evolution, attacking the problem 'along converging lines, leading from solar, stellar, and laboratory investigations'. (Hale, *The Study of Stellar Evolution*, x.)

Huggins' prediction came to pass in the work of HENRY NORRIS RUSSELL of Princeton. Russell had trained under C A Young, who was partial to the theories of Lane and Lockyer, and also became fascinated with the origin and history of double star systems, taking a year of postdoctoral training under George Darwin at Cambridge in 1902 and 1903. Russell saw DOUBLE STARS as the means to explore stellar evolution, mainly in providing a way to determine stellar densities—an indicator of relative age—and set about to find a way to test Lockyer's scheme. Coincidentally, he was hired by the Cambridge University Observatory to assist A R Hinks in a photographic parallax program, and saw in this work another opportunity to perform the test. Parallaxes yielded absolute magnitudes, and by 1908 Russell realized that two very different types of red stars existed in space: small dull ones, and huge luminous ones.

From 1909 through 1913, Russell presented his results in various ways, highlighting the existence of the two classes of red stars, and how they were linked in an evolutionary scheme. Though he initially claimed to the contrary, he was probably aware that he was not alone in this realization. He was the first, however, to use direct means (parallaxes and binary studies) to deduce the existence of giant suns. EJNAR HERTZSPRUNG, a Danish photochemist turned astronomer, had also found that two distinct luminosity classes existed. Prompted by the spectroscopic classification devised by Antonia C Maury at Harvard, Hertzsprung realized that a peculiar subtype, stars exhibiting sharp hydrogen lines and stronger metal lines than their counterparts on the alphabetical Harvard system, all had very small proper motions, yet many were among the brightest stars in the sky. This led him indirectly to the idea that a collateral series of stars existed, and at first he interpreted his findings in an evolutionary scheme. Unlike Russell, he soon dropped any speculation about the evolutionary place of his 'giant' suns.

Russell's 'giant-to-dwarf' theory of stellar evolution

Russell started publishing his findings in 1909 and by August 1910, at a meeting of the Astronomical and Astrophysical Society of America at Harvard, Russell expanded on his theory of stellar evolution, for the first time relating it to Lockyer's, noting that he had rederived it by totally independent means. He also gave it a physical interpretation using the convective models of Lane, Ritter and Emden. Russell's 'giant-to-dwarf' theory envisioned stars beginning as vastly bloated giants in the perfect gas state, contracting under gravity and heating, attaining a density where, deviating now from the perfect gas state, they cooled under continued gravitational contraction. Unlike the dominant linear temperature model of stars descending from nebulae by contraction and cooling, Russell's theory, following Lockyer, viewed stars passing through the observed spectral series twice: once heating, then cooling. Russell also linked his findings to Darwin's model for binary fission. With his first graduate student, HARLOW SHAPLEY, Russell confirmed that what distinguished giants from dwarfs was density, not mass, using eclipsing

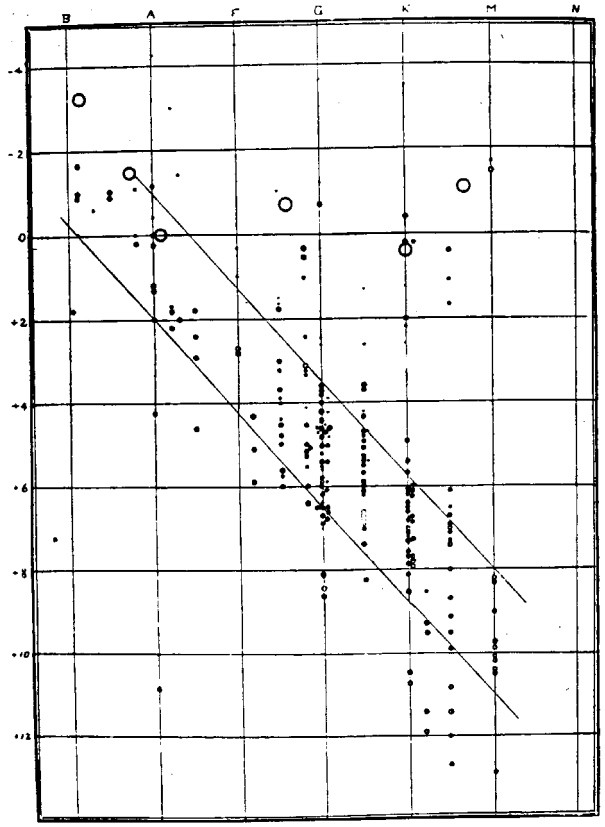

Figure 3. Russell's first diagram based upon direct parallax measurements. The sizes of the dots and circles indicate different ranges of probable error. (Figure 1 from 'Relations between the spectra and other characteristics of the stars' *Popular Astron.* **22** (1914) 285.)

binary data and a new and highly efficient mode of data reduction Russell devised. These efforts culminated in a series of talks, and finally in his famous paper which was presented in 1913 and 1914 in London and then Atlanta. At this time he also devised his version of what has come to be known as the HERTZSPRUNG–RUSSELL (H–R) DIAGRAM, which he presented as the embodiment of his theory of stellar evolution (figure 3).

Russell, however, had a lot of convincing to do. Relative ages deduced from the old linear theory fit nicely Kapteyn's and Campbell's observation of increasing velocity with spectral type, as well as with the observation that the periods of close binary star systems increased with spectral class (and hence age), and with the argument that stars formed in the plane of the Milky Way and then migrated away. Giant suns of late spectral type, the youngest stars on Russell's theory, were found at all galactic latitudes, and the kinematics of both giant and dwarf red stars were similar, and generally larger than those of the earlier spectral classes. In short, Russell's model played havoc with Kapteyn's neat dynamically evolving system. ARTHUR STANLEY EDDINGTON, then at Greenwich, knew this, but also realized that Russell had discovered something fundamental in his diagram. He was therefore anxious to reprint a sample and discuss its implications in his own studies of the structure and evolution of the sidereal universe. He also warmed to the existence of giant stars when he found that he could describe them very nicely using his theory of radiative equilibrium, which he developed over a period of years starting in 1916.

Belief in the existence of giant stars was strengthened with the discovery at Mount Wilson by Walter Sydney Adams and Arnold Kohlschütter of a luminosity effect in spectra, another example of empirical correlation. Although they were asked by Kapteyn to search for interstellar absorption, what they found was that some spectral lines were sensitive indicators of luminosity, a confirmation of what Maury had found and Hertzsprung exploited. They took the next step, however, and used this correlation to develop their spectroscopic parallax technique, and in so doing confirmed the existence of high-luminosity red stars, or giants.

Russell, Adams and others remained concerned, however, about the lack of a rational physical basis for all these empirical correlations between luminosity, spectrum and mass. How closely did stars approximate black-body radiation? What really governed the changes seen in the spectral classes of the stars: temperature, pressure, density, composition? By 1920 Russell's theory of stellar evolution enjoyed greater popularity as Eddington championed giants as perfect gas-spheres in radiative equilibrium.

Eddington's radiative models

Eddington was not an immediate convert. He initially favored the evolutionary interpretation of Kapteyn's star streaming, and worried that Russell's 'giant-to-dwarf' theory destroyed the nice association of 'early type' white and blue stars with nebulae, as the old one could. In 1916, reconsidering the convective gas theory of Emden, partly to explore the behavior of globular clusters, but also to explore the nature of pulsating variables then suggested by Harlow Shapley, Eddington decided that Ritter's (and hence Russell's) theory of stellar evolution could be put on a rational basis using radiative equilibrium to describe the interiors of giant stars, assumed to be in the state of a perfect gas. Studying both the effects of transfer of energy by radiation and the pressure of radiation required a far more sophisticated analysis of the behavior of polytropic gas spheres as radiative engines than Emden had provided. In a series of papers in 1916 and 1917, Eddington established his radiative theory, and showed that he could describe giant stars as they were distributed on Russell's diagram; in effect, he found that the luminosity of a giant star was independent of its stage of evolution, as long as it remained in the perfect gas state. This nicely described Russell's giant branch (figure 3). Eddington's subsequent attention to the theory of polytropes became the core of physical

Dirac House, Temple Back, Bristol, BS1 6BE, UK

and mathematical studies in stellar structure for decades, propelled by his seminal text *The Internal Constitution of the Stars* which appeared in 1926.

Much of Eddington's work was initiated using little more physics than the standard gas laws and the concept of local thermodynamic equilibrium developed by Kirchhoff; as a case in point, he was constantly frustrated by his lack of knowledge of the mechanism of absorption, embodied in the opacity of the gaseous stellar interior. Absorption coefficients derived from Eddington's models based upon astrophysical data differed widely from theoretical values derived by the physicist H A Kramers.

Russell's theory of stellar evolution meshed nicely with Eddington's radiative giants at first, and gave both great popularity in the early 1920s. Probably the high point in their confidence came in 1919, when Russell realized how Eddington's radiative stars, obeying Lane's law and possessing some form of explosive radioactive energy source, could still be stable. Since the specific heat of a mass of gas obeying Lane's law is negative, the more heat it loses, Russell reasoned, 'the hotter it gets; and the more heat that is added to it internally, the colder it becomes!' Stars were, therefore, 'automatically self-limited'. (Russell to Shapley, 5 May; to Webster 9 June 1919, Russell Papers, Princeton.)

Russell's theory fitted Eddington's models until the end of 1924, when Eddington realized, in consequence of his derivation of the theoretical mass–luminosity relationship, that dwarf stars could be in the perfect gas state as well as giants. Astronomers had long known that there was a relationship between the masses and luminosities of stars, but Eddington was the first to show why, on a rational basis. If dwarfs stars were also in the perfect gas state, however, then they would continue to heat upon contraction, and Russell's theory was untenable. The only way to get around this conundrum was to have stars lose mass as they aged.

Time scales, composite models and energy sources

One of the major considerations that significantly altered thinking in the 1920s about the lives of stars and the nature of their structure was the realization some years prior that the gravitational energy of the Sun was woefully inadequate to provide a lifetime of energy output required by geology or biology. Eddington, Russell and others considered two possible mechanisms for sustaining the energy output of the Sun: the annihilation of matter and the transmutation of hydrogen into the heavier elements. Although the latter was compelling for Eddington, mainly because of the careful studies by Aston showing that atomic masses were nearly integral, and by Rutherford's transformation of nitrogen into oxygen, both he and Russell were drawn to the former, because it offered a means to let stars lose mass as they aged. Later in the 1920s, to further bolster his 'giant-to-dwarf' theory, Russell invoked two sources of nuclear energy, one occurring in giant stars and one in dwarfs.

When Hubble's velocity–distance relationship limited the age of the universe to an intermediate time scale of billions of years, the trillions of years of stellar energy provided by matter annihilation was no longer required. An intermediate time scale was also urged by Bart Bok's studies of cluster lifetimes, and, by the mid-1930s as well, with hydrogen accepted as the most abundant element in stellar atmospheres and interiors, and refined knowledge of isotopic masses by Aston confirming that element synthesis for hydrogen would work, that mechanism dominated over matter annihilation. By the end of the decade, with improved knowledge of the structure of the nucleus, physicists Hans Bethe and Carl F von Weizsäcker, a student of W Heisenberg, solved the stellar energy problem by developing the proton–proton and carbon–nitrogen–oxygen cycles.

During the same two decades that the nuclear energy source was sought after, astronomers came to realize that even without knowing the specific mechanism, realistic stellar models had to account for such a source acting in the STELLAR INTERIOR. Some astronomers, including Eddington, argued that fusion processes took place throughout stars, since any star in which the energy generating process depended too strongly on temperature would be unstable. But the trend in the 1930s, led by theorists such as S Rosseland and Ludwig Biermann, a student at Göttingen, was to concentrate the nuclear power source at the stellar center, removing energy by convection. The use of composite polytropic gas-spheres, developed in the late 1920s and early 1930s by theorists such as Thomas G Cowling, E A Milne, Bengt Strömgren and Russell, allowed stars to be described by a series of concentric polytropic distributions. Various solutions existed—one devoid of singularities, a centrally condensed solution, or a collapsed [degenerate] solution which could be fitted together to fit observed characteristics of stars. This new versatility eventually paved the way for Cowling, a student of Milne, to construct a stable point-source model. By the mid-1930s, utilizing a small convective core surrounded by a radiative envelope, his model became the framework within which physicists von Weizsäcker, Bethe, George Gamow and Edward Teller examined nuclear processes in stars, employing the idea that hydrogen was transformed into heavier elements.

The successful search for the source of stellar energy brought nuclear physicists into astronomy. GEORGE GAMOW, Teller, Charles Critchfield, Robert Marshak and others became interested in this new application. Gamow pursued it passionately, writing constantly and excitedly to astronomers requesting observational data, and so became a bridge between the professional worlds of astrophysics and nuclear physics. His greatest contribution was, quite possibly, as host of a conference in Washington, DC in April 1938 which brought the worlds together. Bethe attended, and within months had worked out the physics to show that von Weizsäcker's proton–proton cycle (four hydrogen nuclei fusing into a helium nucleus) could indeed provide the right amount of

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

energy to power the Sun, and that his own 'CNO' cycle, where carbon catalysed four protons to fuse into a helium nucleus, could also account for the greater luminosities of massive main sequence stars.

The landmark contributions of Bethe and von Weizsäcker had immediate impact. Matter annihilation was no longer in vogue, which made the main sequence a locus of equilibrium points, not an evolutionary track. And astronomers could opt for an 'intermediate' time-scale on the order of 10^{10} years, which agreed reasonably with the cosmological and geological time scales. The extreme temperature dependence of these new fusion mechanisms supported Cowling's refinement of the point-source model for stellar structure. Energy generation acted as if it were limited to the centers of stars, and was not distributed throughout the stellar volume. The hydrogen fusion process also required that hydrogen be a significant constituent of stars.

The place of giants in the aging process

During the 1930s, the first suggestions that RED GIANTS could be old evolved stars rather than young stars appeared. In 1932 and 1933, Strömgren explored the theoretical distribution of stars on the H–R diagram, comparing it with observational data for masses, spectra and composition. He found that the position of any star on the diagram was determined solely by its mass and hydrogen abundance. BENGT STRÖMGREN then looked to see how a star's position on the H–R diagram would change as its hydrogen content diminished, assuming with others that hydrogen was expended in some yet unknown nuclear process to power the stars. He found that evolutionary tracks lay across lines of equal hydrogen abundance, and as hydrogen was consumed, stars would 'leave' the main sequence and head up and to the right, or toward the region of the giant red stars. He stated explicitly that as stars aged, they would expand (figure 4).

In the late 1930s GERARD KUIPER and Strömgren were hired by Otto Struve to the Yerkes Observatory staff. Kuiper, primarily a double star man, was also very interested in re-examining the H–R diagrams of galactic clusters that Robert Trumpler had produced. Stimulated by Strömgren's theoretical work on diminishing hydrogen content, Kuiper placed many clusters on the same diagram, and found that their main sequences coincided at lower luminosities and diverged for the higher luminosities. The divergence was systematically correlated with the consumption of hydrogen and all the divergences led to the giant region. Kuiper only noted that these divergences were somehow clues to evolutionary change. Nor did he discuss explicitly the direction of evolution, as Strömgren had before him. There was simply not enough physics available, and observational data for masses and abundances were far from consistent. Kuiper, an observational astronomer, was not able to create a convincing picture.

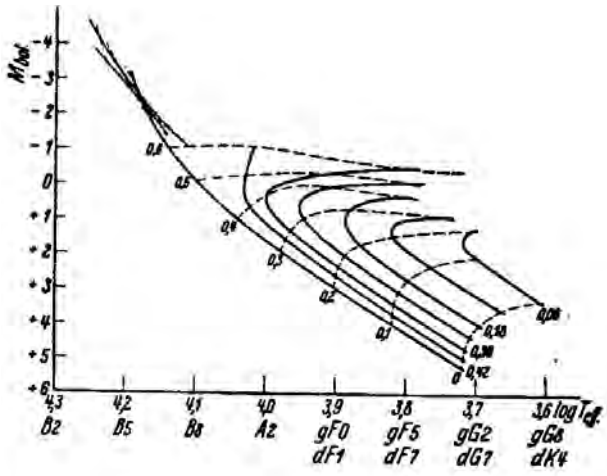

Figure 4. Theoretical distribution of stars by constant hydrogen content (full curves) and by constant mass (broken curves). (From figure 4 in Strömgren B 1933 'On the interpretation of the Hertzsprung–Russell-diagram' *Z. Astrophys.* **7** 244.)

At the end of the decade and into the early 1940s, continued exploration of various inhomogeneous stratified models, first suggested by ERNST J ÖPIK, led Gamow, S CHANDRASEKHAR and others to consider what happens when hydrogen is exhausted in the stellar core, and hydrogen fusion commences in a shell surrounding the core. Skeptical about Gamow's work, Chandrasekhar, with Louis R Henrich and Mario Schönberg, developed true hydrogen shell burning models. These models demonstrated for the first time that changes in composition were related to some type of evolution away from the main sequence. Out of this came the famous Schönberg–Chandrasekhar limit, which placed an upper limit to the size of the exhausted core (not to be confused with Chandrasekhar's earlier study of the limiting masses of white dwarfs).

In the post-World War 2 era, the continued application of nuclear physics to the problem of stellar energy, along with increasingly versatile models made possible by improved methods of numerical computation aided by high-speed computers, led to an improved ability to describe stars in all stages of stellar evolution, from red giants to white dwarfs. Along the way, several fundamental adjustments in theory and technique aided the process of change. In the 1920s and early 1930s, analytical methods of modelling still dominated in theoretical astrophysics in the manner Eddington established them. But by the mid- to late 1930s, younger theorists in Europe and the United States started to build stellar models by numerical techniques making its easier to fit together composite polytropic layers. Furthest from the analytical tradition so strong at Cambridge, Russell always preferred numerical calculations, whereas Chandrasekhar, breaking tradition with his mentors Milne and Eddington, used both numerical and analytical techniques.

In contrast to Eddington, physicists such as George Gamow actively sought out astrophysicists to engage them in the search for solutions to major questions in stellar structure and evolution. After Bethe and von Weizsäcker established the hydrogen transmutation processes active in stars, and Strömgren provided astrophysical confirmation of the importance of hydrogen content, it was Gamow, Chandrasekhar, Baade and then MARTIN SCHWARZSCHILD who opened avenues of cross-disciplinary communication to establish the intellectual infrastructure out of which the modern picture of post-main sequence stellar evolution would emerge in the 1950s. As a first step, a theoretical group led by Schwarzschild in Princeton (where Lyman Spitzer and John Wheeler were close at hand), and an observational group led by Walter Baade at Mount Wilson, made a combined attack on the relative ages of star clusters, equating their appearance on the H–R diagram to theoretical models of stars with exhausted hydrogen cores. The end result in the mid-1950s was that giant stars were no longer thought to be stars in pre-main sequence formation, but were post-main sequence stars with hydrogen-exhausted cores gaining power from hydrogen burning in shells surrounding their cores. Two major problems had to be cleared up, however, before the framework of the picture was complete.

In April 1952, Cornell nuclear physicist EDWIN SALPETER, who had recently become attracted to the field while in residence at Caltech working with William A. Fowler, Jesse Greenstein and Baade, reviewed concepts of stellar energy and evolution, and found the latter in a general state of confusion regarding where white dwarfs, red giants and intrinsic variables were situated in the evolutionary process. Indeed, what maintained red giants in their vastly bloated state of existence? All stars that had exhausted the supply of hydrogen available for fusion, assumed to be rotating and in a well-mixed state, were still thought to resume evolving somehow by contraction. There were other problems too, such as how to form the heavy elements. Bethe and von Weizsäcker's hydrogen fusion mechanisms, the proton–proton and CNO cycles, could only go so far, and neither of them, nor a speculated process of neutron capture by helium in the BIG BANG, postulated by Alpher, Herman and Gamow in the 1940s, could produce stable elements of atomic mass 5. In 1950, Enrico Fermi and A Turkevich at Chicago showed that no elements heavier than helium could have been produced in the Big Bang, making element synthesis the domain of the stars. Soon after, Öpik and Salpeter independently solved the mass 5 problem, showing that the fusion of three helium nuclei could form carbon. They also established that helium fusion was capable of acting as a new source of energy after hydrogen exhaustion.

Salpeter's contribution has been called the 'triple-alpha process' wherein helium is transmuted into heavier elements. With it, astrophysicists could begin to discuss what is essentially the second step to the modern picture of stellar evolution, where a poorly mixed star consuming hydrogen becomes inhomogeneous as helium is produced in its core and it becomes incapable of burning more hydrogen. When the core grows to some 10 per cent of the stellar mass, it becomes unstable. The unstable core contracts and heats causing the remaining stellar envelope to expand and cool, turning a main sequence star into a red giant. Mario Schönberg, Chandrasekhar, Öpik, A Sandage and Schwarzschild all contributed to this modern picture by 1955, which highlighted the importance of solving the problem of how elements beyond iron could be synthesized in the cores of stars. This was solved by a collaboration of an observational astrophysicist, two theoretical astrophysicists, and a nuclear physicist: Margaret Burbidge, Geoffrey Burbidge, Fred Hoyle and William Fowler (known as 'B^2FH'). Spurred on in 1956 and 1957 in their pursuit of an alternative to the Big Bang as a site for the origin of the elements—in the centers of stars as opposed to the original big bang—they developed a set of neutron capture processes for building the heaviest elements in stars, and inaugurated the modern study of nucleosynthesis. In the decades since 1955, astrophysicists have been working out the details, mainly with the aid of high-speed computing machines which have made numerical techniques highly effective tools for the study of stellar structure and evolution.

In 1951, as his part in surveying a century of science, W H MCCREA argued that the present state of the study of the constitution and evolution of the stars was possibly:

> ... the crowning achievement of the century in physical science. For it has explained the properties of a star in terms of those of the fundamental particles of laboratory physics, and in doing so it has employed every fundamental advance in pure physics and has depended upon observations made with the aid of all the resources of physical technology. (McCrea 1951, p 136.)

McCrea's point was, however, to argue that a history of the subject is difficult to treat in concise fashion, as it requires many diversions to appreciate the necessary advances on many fronts lurking in the most arcane corners of physics and technology. McCrea, a theorist and a younger member of the mathematical physics circle centered on Eddington, Milne and R H Fowler, considered mainly theoretical tools such as quantum and nuclear physics. But the tools of the astrophysicist include the techniques of the spectroscopist in the laboratory as well as at the telescope, and, more recently, in the post-World War 2 era, the expertise of electronics, both in the development of photoelectric and solid-state devices, in radio astronomy as well as in the multitude of non-visible astronomies, and in nuclear physics, as practised by academic theorists, experimentalists and military laboratories. Only when all these facets of the problem are addressed by historians and astronomers alike will a satisfactory history emerge.

Struve, Wilhelm (1793–1864)

Born in Altona, Germany, became professor of astronomy at Dorpat (now Tartu), Estonia, and director of the Dorpat Observatory. Using FRAUNHOFER's refractor he began his work on double stars. He became director of Pulkova (Pulkovo) Observatory near St Petersburg, Russia, which was constructed to his specifications by Tsar Nicholas I and became arguably the most productive observatory of the time in the world. He published a catalog (*Mensurae Micrometricae*, 1837) of over 3000 binary stars, and carried out one of the first determinations of stellar distance, the parallax of Vega (1837), a star that he selected for investigation for this purpose because it had a large proper motion and was bright, thus indicating that it might be nearby. The measurements were not believed, especially since he published a discordant value, twice as large, only three years later. It was not until Bessel measured the parallax of 61 Cygni in 1838, and showed that the measurements contained the expected patterns, that astronomers accepted that a parallactic measurement had been reliably achieved.

Subaru Telescope, Hawaii

The Subaru Telescope, Hawaii is an 8.2 m aperture optical infrared telescope being operated by the NATIONAL ASTRONOMICAL OBSERVATORY, JAPAN (NAOJ) atop Mauna Kea, Hawaii. It is one of the new-generation telescopes with an actively controlled large monolithic mirror, and has been producing testing-phase observational results on solar system, star formation, active galactic nuclei and quasars, group of galaxies, gravitational lensing and cosmology, etc since its first-light in January 1999. The Subaru Telescope aims to explore the universe more deeply and widely with its very high imaging capability and rich observational instruments mounted at its four foci. After nine years of construction since 1991, the Subaru Telescope will start its open-operation in the year 2000. The Subaru Telescope Base Facility at Hilo, Hawaii holds 50 staff, 20 visiting members, a large computer system and laboratories for developmental works.

Subatomic Particles

Particles that are smaller than atoms. Subatomic particles include the constituent components of atoms and particles that are produced in nuclear reactions or in interactions between other subatomic particles. They are also found among cosmic rays.

Particles are characterized by their physical properties, in particular: mass, charge and spin. Although the masses of subatomic particles may be expressed in conventional mass units (kg), because of the equivalence between mass (m) and energy (E) that is a consequence of the special theory of relativity (i.e. $E = mc^2$, where c denotes the speed of light), the equivalent energy (expressed in electronvolts) is usually quoted as the 'mass' of the particle, even although, strictly speaking, mass (m) $= E/c^2$. The unit of charge is the charge on the electron (1.602×10^{-19} coulomb). Spin is the quantity of angular momentum associated with a particle (the particle may be visualized as spinning around an axis) or an atomic nucleus and takes values given by $nh/2\pi$, where h is the Planck constant and $n = \frac{1}{2}, 1, \frac{3}{2}, 2$, etc.

Particles are subdivided into bosons (particles with n equal to an integer: 1, 2, ...) and fermions (particles with half-integral values of spin: $\frac{1}{2}, \frac{3}{2}, \ldots$). Fermions obey the Pauli exclusion principle, while bosons do not. Among the bosons, the gauge bosons (particles that transmit the fundamental forces) constitute an important group. The fermions may be subdivided into hadrons (particles that are composed of quarks and are acted on by the strong nuclear interaction) and leptons (particles that do not contain quarks and which do not experience the strong nuclear interaction). The hadrons are subdivided into baryons (particles composed of three quarks) and mesons (composed of quark–antiquark pairs). Among the baryons, an important class is the nucleons (protons and neutrons). Electrons and neutrinos are examples of leptons.

The term 'elementary particle' is sometimes applied to particles that have no internal structure and which cannot be broken down into more basic constituent particles. However, because some particles that were at one time considered to be 'elementary' (e.g. protons) are now known to consist of quarks, the term 'fundamental particle' is sometimes used to distinguish those (leptons, quarks and gauge bosons, so far as is known at present) that are genuinely basic particles.

See also: antimatter, atom, baryons, cosmic rays, elementary particles, electron, electronvolt, fundamental forces, fundamental particles, gauge bosons, hadrons, leptons, matter, mesons, neutron, neutrinos, Pauli exclusion principle, photon, proton, quark.

Submillimeter Telescope Observatory

The Submillimeter Telescope Observatory (SMTO), a collaboration of the MPIfR and Steward Observatory, operates the 10 m Heinrich Hertz Telescope (HHT) for observations in the millimeter and submillimeter wavelength range. The SMTO is located at an altitude of 3186 m on top of Mount Graham, Arizona. The HHT has a very accurate surface (12 μm rms) and it is the first telescope to use a hot-electron bolometric mixer receiver for astronomical observations at frequencies of 690 and 810 GHz.

Sudbury Neutrino Observatory

The Sudbury Neutrino Observatory (SNO) studies neutrinos from the Sun, supernovae and other astrophysical sources. The detector is situated 2000 m underground in an active nickel mine near Sudbury, Ontario, Canada and observes Cerenkov light from neutrinos interacting with 1000 tonnes of ultra-pure heavy water (D_2O) surrounded by 7000 tonnes of light water shielding. Several different neutrino interactions are used to observe the flux and energy spectrum of electron neutrinos reaching the Earth from the solar core; and the total flux of all three neutrino types, to determine if neutrino flavor change (indicative of finite neutrino rest mass) has occurred. The project involves 100 scientists from Canada, USA and UK and began observations in May 1999.

Suidas (tenth century)

Greek encyclopedist. In the course of reading Suidas's *Lexicon*, EDMOND HALLEY mistakenly connected the naming of the Saros cycle of 223 synodic months by the tenth century Greek lexicographer Suidas with the eclipse cycle of the same period. The solar eclipse cycle is thus now known by the name that Suidas used for another phenomenon. Halley's mistake accounts for the historical confusion that the Saros cycle of solar eclipses was discovered by the Babylonians (it was not).

Summer Triangle

A conspicuous asterism which dominates the northern sky during summer, comprising the bright stars Vega (α Lyrae, apparent magnitude 0.03), Deneb (α Cygni, apparent magnitude 1.25) and Altair (α Aquilae, apparent magnitude 0.76). Vega, by far the most brilliant star in the northern summer sky, is also the brightest to pass overhead (within 13° of the zenith), with the exception of Capella (α Aurigae) which is a winter object.

The Summer Triangle is crossed by a double band of the Milky Way (the galactic equator passes almost axially through the triangle). There are many rich star fields and interesting objects within its borders, but few bright stars. Only two stars of third magnitude or brighter are found inside the triangle (β and γ Cygni), and three more along its sides. It therefore has a somewhat empty appearance to the unaided eye, but is a rewarding area for examination with binoculars or a small telescope.

Sun

The nearest star to the Earth and central body of the solar system. A main-sequence, yellow dwarf of spectral type G2 V, mass 1.989×10^{30} kg, diameter 1392 000 km, luminosity 3.83×10^{26} W and absolute visual magnitude +4.82, the Sun is the only star whose surface and outer layers can be studied close up. From the Earth, a mere 149 600 000 km away, the Sun's disk subtends an angle of about 30′ and its apparent visual magnitude is −26.78.

The Sun is composed mainly of hydrogen (about 70% by mass) and helium (about 28%), with a small proportion (about 2%) of heavier elements. In its central core, which is thought to be about 200 000 km in diameter, the maximum density is about 148 000 kg m^{-3} (so that almost 30% of the Sun's mass is contained in barely 3% of its volume). Here the temperature is about 15 000 000 K and hydrogen nuclei fuse together to form helium nuclei in the proton–proton (p–p) chain reaction. The energy liberated by the 4.4×10^9 kg of mass lost per second in this reaction is radiated through the radiative zone to within about 200 000 km of the surface, where, the temperature having fallen to about 1000 000 K, convection takes over. The convective zone extends to just below the surface, or photosphere, which is an opaque layer several hundred kilometers thick that represents the boundary between the solar interior and solar atmosphere.

The photosphere has a mottled appearance called granulation, which represents the tops of convection currents from below. Within the granulation dark markings called sunspots appear, surrounded by lighter faculae which are visible well away from the brighter central region of the Sun's disk. Sunspots and faculae mark the position of intense, localized magnetic fields, and their numbers and mean latitude change over an average period of approximately 11 years—the so-called sunspot cycle. Observation of the passage of sunspots across the Sun's disk reveals a differential rotation, the synodic period increasing with heliographic latitude from 26.87 days at the equator to 29.65 days at $\pm 40^\circ$, beyond which sunspots are seldom seen. The mean synodic period is 27.2753 days (sidereal period 25.38 days), which corresponds to the actual period at about $\pm 15^\circ$. Spectroscopic measurements show that the rotation period continues to increase with increasing latitude above $\pm 40^\circ$ and that it decreases with height above the photosphere, except at the equator, where the periods are approximately the same. The reason for this differential rotation is not known.

The temperature of the photosphere decreases from about 6000 K at its base to about 4000 K at the so-called temperature minimum, where it merges with the chromosphere. The chromosphere is a stratum of gases a few thousand kilometers thick, in which the temperature increases (as a result of processes such as mechanical dissipation) to around 50 000 K as the density decreases exponentially with height. It is the realm of cloud-like filaments, or prominences, which have a higher density and lower temperature than their surroundings, and of short-lived explosive events called flares. Sunspots, most filaments/prominences and flares constitute active regions, which are the most obvious manifestations of solar activity and are characterized by enhanced emission at x-ray, extreme ultraviolet and radio wavelengths.

Above the chromosphere lies the transition region, only several hundred kilometers thick, in which the temperature increases again, to around 500 000 K. Beyond this lies the corona, which attains a maximum temperature of about 2000 000 K at a height of about 75 000 km and extends for many million kilometers into the interplanetary medium, where the solar wind carries a stream of atomic particles to the depths of the solar system.

The Sun is believed to possess a weak general magnetic field, but is has proved difficult to disentangle this from the remnant magnetic fields of sunspots. The intense, localized magnetic fields determine the configuration of sunspots, active region filaments and other associated phenomena, the occurrence of short-lived events such as flares, and even the structure of the solar corona.

The age of the Sun is about 4.6×10^9 years and it is expected to maintain its present energy output for at least a similar period, whereafter it will expand to become a red giant and then expel its outer layers, leaving a white dwarf surrounded by a planetary nebula.

Sun and Solar–terrestrial Physics

The Sun is of central importance in astronomy. On the one hand, many basic processes that occur throughout the cosmos may be well observed in the Sun and, on the other hand, the Sun acts as a source of the radiation and plasma emissions that affect the Earth in many ways. The study of the interaction of the Sun and its solar wind with the Earth is the burgeoning field of solar–terrestrial physics. The magnetospheres of other planets act as probes for the solar wind. However, many of the fundamental processes, such as how the Sun's magnetic field is generated, how its atmosphere is heated, how solar flares occur and how the solar wind is accelerated, are only just beginning to be understood. This article attempts an overview of the Sun and solar–terrestrial physics and links the individual articles in this encyclopedia into the big picture.

The Sun

The Sun is of course the nearest star, seen in greatest detail (SUN: BASIC PROPERTIES). The total radiation (SOLAR IRRADIANCE) from the Sun is not constant but, like a variable star, the Sun varies over a variety of timescales. Treated as a star whose properties are more accurately known than most (SUN AS A STAR), the Sun has become a pivotal point in discussion of the abundance of the elements (SOLAR ABUNDANCES) and stellar evolution (SOLAR EVOLUTION). The SOLAR MAGNETIC FIELD plays a key role in many aspects of Solar Physics. It is measured through polarimetry (SOLAR MAGNETIC FIELD: INFERENCE BY POLARIMETRY) and the Zeeman and Hanle Effects (SOLAR MAGNETIC FIELD: ZEEMAN AND HANLE EFFECTS). The solar magnetic field undergoes a cyclic behavior with a period of roughly 22 years (SOLAR CYCLE). Many features of solar activity follow this cycle.

The Sun, indeed most of the Universe, is in the fourth state of matter—the so-called plasma state—in which a gas is so hot that it has become ionized. Its behavior differs from that of a normal gas mainly because it interacts in a complex and subtle way with any magnetic field that is present. Such an interaction is described by the theory of MAGNETOHYDRODYNAMICS, which applies when the ionized particles are much closer than the length-scales of interest, so that the plasma may be regarded as a continuous medium. The magnetic fields are generated within solar and planetary interiors in a self-sustaining way by a process described by DYNAMO THEORY, although the parameter regimes and driving processes are rather different in the GEODYNAMO and in stellar dynamos (DYNAMOS: SOLAR AND STELLAR).

When the force produced on a plasma by a magnetic field dominates all other forces (as is the case, for example, in the upper solar atmosphere), and the magnetic field is in equilibrium with itself, it is said to be a FORCE-FREE MAGNETIC FIELD. Force-free structures can be highly complex and, when they are either twisted or braided around one another, they possess so-called MAGNETIC HELICITY. Equilibrium magnetic fields may be subject to a wide variety of MAGNETOHYDRODYNAMIC INSTABILITIES, which may produce either a large-scale dynamic behavior or a small-scale structuring of the plasma. In the solar interior, magnetic flux tubes tend to be lighter than their surroundings and so rise by an effect called MAGNETIC BUOYANCY. Also, when heated sufficiently from below, a plasma tends to exhibit turbulent motions due to a convective instability, which, when it interacts with a magnetic field, is known as *magnetoconvection* (see MAGNETOHYDRODYNAMICS: MAGNETOCONVECTION).

In most of the cosmos, magnetic fields are attached or 'frozen' to the plasma and move around with it. The exception is in singular regions where MAGNETIC RECONNECTION can occur and magnetic energy is converted into other forms such as heat, kinetic energy and fast-particle energy. The energy conversion occurs when magnetic field lines are carried into the singularity, broken and rejoined. Several different modes of oscillation (MAGNETOHYDRODYNAMIC WAVES) can be supported in plasmas and are important for transporting energy from one location to another. Several magnetohydrodynamic processes are also crucial in astrophysical circumstances (MAGNETOHYDRODYNAMICS OF ACCRETION DISKS and MAGNETOHYDRODYNAMICS OF ASTROPHYSICAL WINDS).

SOLAR SPECTROSCOPY AND DIAGNOSTICS are invaluable in determining many properties of the plasma such as temperature, density and velocity. The theoretical background lies in atomic physics (SOLAR SPECTROSCOPY: ATOMIC PROCESSES). To access the most complete information about what is happening, astronomers make multiwavelength observations across the whole spectrum (SOLAR SPECTROSCOPY: COHERENT PLASMA EMISSION, SOLAR SPECTROSCOPY: CONTINUUM RADIO EMISSION, SOLAR SPECTROSCOPY: INFRARED EMISSION, SOLAR SPECTROSCOPY: VISIBLE EMISSION, SOLAR SPECTROSCOPY: ULTRAVIOLET AND EXTREME ULTRAVIOLET EMISSION and SOLAR SPECTROSCOPY AND DIAGNOSTICS: X-RAY EMISSION).

Because of the Sun's brightness, its heat and the dynamic range of its phenomena (which may be time-variable), a wide range of special instrumentation has been employed to study the Sun, both from the ground and from space (SOLAR TELESCOPES AND INSTRUMENTS: GROUND and SOLAR TELESCOPES AND INSTRUMENTS: SPACE). Of the space missions, those of particular interest have been the American SKYLAB satellite (1973–1974), the Japanese YOHKOH mission (August 1991 to the present), the European Space Agency/NASA SOHO mission (December 1995 to the present), and the American TRACE mission (April 1998 to the present). For analysing data, the SOLARSOFT package is particularly useful.

Of growing interest is the link between activity on the Sun and effects on the Earth's atmosphere—the SOLAR–TERRESTRIAL CONNECTION. A subtle coupling exists between variations in the *solar wind*, the Earth's magnetic environment or *magnetosphere*, the ionized or plasma part of the Earth's atmosphere (the *ionosphere*) and the unionized or *neutral atmosphere* (SOLAR–TERRESTRIAL CONNECTION: COUPLING BETWEEN SOLAR WIND, MAGNETOSPHERE, IONOSPHERE AND NEUTRAL ATMOSPHERE). One consequence is that the Earth's

climate is variable, driven by changes in the Sun (SOLAR–TERRESTRIAL CONNECTION: LONG-TERM AND SHORT-TERM CLIMATE VARIABILITY). Satellite observations are being used to predict the effect of the Sun's activity from day to day on the solar wind and the magnetosphere (SOLAR–TERRESTRIAL CONNECTION: SPACE WEATHER PREDICTIONS). Looking outwards from the Sun, there is also enormous interest in what the Sun can tell us about other stars and vice versa (the SOLAR–STELLAR CONNECTION) and in particular about solar-type stars (SOLAR–TERRESTRIAL CONNECTION: ACTIVITY AND BRIGHTNESS CHANGES OF SOLAR-TYPE STARS).

The solar interior and atmosphere

There are three main regions of the solar atmosphere, namely, the surface layer of the Sun (the SOLAR PHOTOSPHERE), the overlying hotter and rarer CHROMOSPHERE with a temperature of about 10^4 K and the much hotter (about 10^6 K) and rarer CORONA, which stretches out to the Earth and beyond. The plasma that possesses temperatures between 10^4 K and 10^6 K comprises the SOLAR TRANSITION REGION.

For the SOLAR INTERIOR a series of standard models has been developed (SOLAR INTERIOR: STANDARD MODELS), based on the best available theories of the properties of the interior material (SOLAR INTERIOR: EQUATION OF STATE AND OPACITY). As a result of the high temperatures and pressures, nuclear energy is released in the solar interior (SOLAR INTERIOR: ENERGY GENERATION) with the release of neutrinos (SOLAR INTERIOR: NEUTRINOS). The plasma in the outer 30% of the solar interior is convectively unstable (SOLAR INTERIOR: CONVECTION ZONE and SOLAR INTERIOR: CONVECTION THEORY). Within the SOLAR INTERIOR: CONVECTION ZONE FLUX TUBES respond to the resulting turbulent motions as well as differential rotation and Coriolis forces. Eventually, from the SOLAR INTERIOR: EMERGING MAGNETIC FLUX TUBES may create sunspots when their flux is large enough.

The Sun rotates (SOLAR INTERIOR: ROTATION). The rotation rate is faster at the equator than the poles and possesses a surprising variation with depth. Gross properties of the SOLAR INTERIOR: SOLAR DIAMETER, OBLATENESS AND TEMPERATURE have dependences on the rotation rate.

Our understanding of the solar interior has been revolutionized by the realization that the Sun is globally oscillating in thousands of modes of vibration (SOLAR INTERIOR: HELIOSEISMIC OBSERVATIONS). Observations have been made both from ground-based networks (BISON NETWORK, GLOBAL OSCILLATION NETWORK GROUP) and the SOHO satellite. The observations lead to properties of the solar interior (SOLAR INTERIOR: HELIOSEISMOLOGY DATA INVERSIONS). HELIOSEISMOLOGY THEORY has been developed in detail, including techniques for inferring properties close to the surface (SOLAR INTERIOR: LOCAL HELIOSEISMOLOGY). MAGNETOHYDRODYNAMICS is used for deducing the influence of magnetic fields (SOLAR INTERIOR: INFLUENCE OF MAGNETIC FIELDS).

For the structure of the atmosphere, empirical models have proved invaluable. Many properties of the SOLAR PHOTOSPHERE change systematically across the face of the Sun (SOLAR PHOTOSPHERE: CENTER-TO-LIMB VARIATION), and on a smaller scale: *faculae* are small regions that are brighter than normal (SOLAR PHOTOSPHERE: FACULAE) and *filigree* are bright crinkle-shaped ribbons (SOLAR PHOTOSPHERE: FILIGREE). Convection exists on several scales, about 1 Mm (SOLAR PHOTOSPHERE: GRANULATION), a larger scale (SOLAR PHOTOSPHERE: MESOGRANULATION) and an even larger scale of 15 Mm (SOLAR PHOTOSPHERE: SUPERGRANULATION). Over most of the solar surface the magnetic field is far from uniform, being concentrated into intense SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES at the edges of supergranule cells. In the interior of such cells, the magnetic fields are tangled by convection (SOLAR PHOTOSPHERE: INTRANETWORK AND TURBULENT MAGNETIC FIELDS).

The CHROMOSPHERE is even more non-uniform. A bright *network* surrounds the supergranule cell boundaries (CHROMOSPHERE: NETWORK). Around sunspots the magnetic field is a few hundred gauss and is associated with a brightening of the surrounding region (SOLAR CHROMOSPHERIC PLAGE). Transient brightenings occur near sunspots at the feet of surges (SOLAR CHROMOSPHERE: ELLERMAN BOMBS). Bipolar magnetic flux tubes break through the solar surface (CHROMOSPHERE: EMERGING FLUX REGIONS). Dark *fibrils* due to dense plasma along a *canopy* of magnetic flux tubes cross the interior of supergranule cells (CHROMOSPHERE: FIBRILS and CHROMOSPHERE: CANOPY). Jets of plasma (CHROMOSPHERE: SPICULES) are ejected along flux tubes upwards at the network boundary. SOLAR CHROMOSPHERIC OSCILLATIONS are observed and are related to one of the possible sources of the high temperatures in the chromosphere (CHROMOSPHERE: HEATING MECHANISMS).

The SOLAR TRANSITION REGION is highly dynamic and it is not easy to develop theories (TRANSITION REGION MODELS). There is a variety of flows and small-scale high-velocity features (TRANSITION REGION FLOWS) and TRANSITION REGION: EXPLOSIVE EVENTS. Elemental abundances vary by about a factor of four from place to place. Elements whose neutral atoms have ionization potential larger than about 10 eV are less abundant than those whose neutral atoms are more easily ionized (TRANSITION REGION: FIRST IONIZATION POTENTIAL EFFECT).

The CORONA possesses several different types of structure. CORONAL HOLES have magnetic fields that are open into interplanetary space. POLAR PLUMES are dense rays in coronal holes outlining the magnetic field. CORONAL LOOPS have magnetic field lines that have both ends anchored to the solar surface. Small bright regions (SOLAR CORONA: X-RAY BRIGHT POINTS) occur where magnetic fields are reconnecting. Streams of plasma (SOLAR X-RAY JETS) are accelerated to several hundred km s^{-1} by magnetic reconnection. Large-scale structures (CORONAL STREAMERS) are closed below a large fraction of a solar radius above the limb and are open above that height.

The solar corona was traditionally seen only during an ECLIPSE but now can be observed by CORONAGRAPHS from the ground and direct by EUV and x-ray telescopes from space. An important problem is the nature of CORONAL HEATING MECHANISMS. Part of this has been solved, since x-ray bright points are now known to be heated by driven

Dirac House, Temple Back, Bristol, BS1 6BE, UK

magnetic reconnection, but it has not yet been established whether coronal loops and coronal holes are heated by magnetic waves of some kind or by magnetic reconnection in many small current sheets.

Solar activity

The term *solar activity* refers to a wide range of transient solar phenomena that vary in complex ways with the SOLAR CYCLE. SUNSPOTS are dark regions in the photosphere where large thousand-gauss magnetic flux tubes break through the surface. SOLAR ACTIVE REGIONS surround sunspot groups and have fields of a few hundred gauss. SOLAR PROMINENCES are huge flux tubes up in the corona, containing a vertical sheet of plasma at chromospheric temperatures. SOLAR FLARE OBSERVATIONS show how enormous releases of magnetic energy are often related to the eruption of prominences from active regions. SOLAR CORONAL MASS EJECTIONS are large-scale eruptions of mass associated with prominence eruptions, either from active regions or outside active regions.

A variety of SOLAR ACTIVITY INDICES has been proposed for measuring the strength of solar activity. Indeed, solar activity may be traced back many centuries (SOLAR ACTIVITY: LONG-TERM RECORDS). SOLAR ACTIVITY COMPLEXES are active regions that tend to recur in the same location and form. Whereas active regions, like sunspots, occur only in two zones of latitude north and south of the equator, much smaller bipolar regions appear over the whole solar surface at a rate of typically one region per 27^2 Mm^2 per day (SOLAR ACTIVE REGIONS: EPHEMERAL). Coronal mass ejections produce a wave-like disturbance that propagates ahead of the mass and whose intersection with the solar surface sometimes shows up as MORETON WAVES moving outwards from the site of the eruption.

Prominences are referred to as 'filaments' when observed on the disk, and they form in SOLAR FILAMENT CHANNELS, where the magnetic field is mainly horizontal and directed along a reversal in the sign of the normal component of the field at the solar surface. Quiescent prominences can last for many months but are also of shorter duration (SOLAR PROMINENCES: ACTIVE). Important questions concern SOLAR PROMINENCE FORMATION and SOLAR PROMINENCE FINE STRUCTURE. SOLAR PROMINENCE OSCILLATIONS of various kinds are often observed and their sense of twist exhibits a puzzling global pattern (SOLAR PROMINENCES: CHIRALITY).

SOLAR FLARE CLASSIFICATION has settled to a standard method and much effort has been expended on SOLAR FLARE FORECASTING. The behavior of SOLAR FLARE MAGNETIC FIELDS is crucial to an understanding of SOLAR FLARE MODELS and SOLAR FLARES: PARTICLE ACCELERATION MECHANISMS. The connection between solar flares and coronal mass ejections was for a while a matter of heated debate (SOLAR FLARES: RELATION TO CORONAL MASS EJECTIONS). Solar flares often produce small ejections of mass called *surges* and occasionally give a continuum brightening in the photosphere (SOLAR FLARES: WHITE LIGHT). A solar flare has several phases. Before the flare a prominence starts to rise slowly. The flare rapidly develops in a few minutes, with a rapid acceleration of *nonthermal electrons*, sometimes producing *gamma rays*. During the *main phase*, the energy release continues for several hours (SOLAR FLARES: PREFLARE PHASE, SOLAR FLARES: IMPULSIVE PHASE, SOLAR FLARES: NONTHERMAL ELECTRONS, SOLAR FLARES: GAMMA RAYS, SOLAR FLARES: MAIN PHASE). In addition, a flare produces different kinds of radio emission (SOLAR FLARES: RADIO BURSTS).

Sunspots often start as small dark patches called SUNSPOT PORES and develop into several different types (SUNSPOT CLASSIFICATION). The central part of the sunspot is dark and is called the *umbra* (SUNSPOT UMBRA: STRUCTURE AND EVOLUTION). The umbra is slightly depressed and so changes its appearance as a sunspot rotates across the solar disk (SUNSPOTS: WILSON EFFECT). The umbra is surrounded by an annulus (the *penumbra*) with radial striations, since the magnetic field is more horizontal (SUNSPOT PENUMBRA: STRUCTURE AND ACTIVITY). The penumbra exhibits a radial outflow (SUNSPOTS: EVERSHED EFFECT). SUNSPOT OSCILLATIONS AND SEISMOLOGY are used to infer the structures of sunspots and SUNSPOT MODELS for the structures have been developed in detail. SUNSPOT MAGNETIC FIELDS tend to be vertical at the centers of sunspots and then to become more horizontal as one moves outwards from the axis, as the vertical flux tube spreads out through the photosphere. SUNSPOT EVOLUTION follows a standard pattern. A radial *moat flow* of plasma away from a sunspot carries magnetic flux outwards (SUNSPOTS: MOVING MAGNETIC FEATURES AND MOAT FLOW).

The solar heliosphere

The *solar wind* is the outwards expansion of the corona from the Sun. It is described in a general article (SOLAR WIND: GLOBAL PROPERTIES). SOLAR WIND: THEORY describes its structure and SOLAR WIND ACCELERATION how it gains in velocity. The SOLAR WIND COMPOSITION and SOLAR WIND KINETIC PROPERTIES are highly complex. Both *waves* and *turbulence* and *shock waves* make up its structure (SOLAR WIND PLASMA WAVES, SOLAR WIND TURBULENCE, SOLAR WIND SHOCK WAVES AND DISCONTINUITIES) and the SOLAR WIND: MAGNETIC FIELD is highly variable. Especially interesting is the behavior out of the ecliptic plane as measured by the only satellite to orbit in that region (SOLAR WIND: ULYSSES).

Neighboring streams that are flowing out from the Sun interact at their boundaries (SOLAR WIND: COROTATING INTERACTION REGIONS). Accelerated particles (SOLAR WIND: ENERGETIC PARTICLES) of many types are observed; they produce bursts of radio waves (SOLAR WIND: INTERPLANETARY RADIO BURSTS) which are a valuable diagnostic (SOLAR WIND: RADIO TECHNIQUES FOR PROBING). COSMIC RAYS may give rise to showers of electrons and other particles when they impact on the Earth's atmosphere (COSMIC RAYS: EXTENSIVE AIR SHOWERS). Their propagation has been modeled in detail (COSMIC RAYS: PROPAGATION IN THE HELIOSPHERE). Those with energies up to 100 MeV and which lie between the energies of normal heliospheric particles and galactic cosmic rays are known as ANOMALOUS COSMIC RAYS.

The solar wind is rooted in the corona (SOLAR WIND: CORONAL ORIGINS) and is sensitive to solar activity (SOLAR

WIND: MANIFESTATIONS OF SOLAR ACTIVITY). Venus interacts with the solar wind as it flows through the heliosphere (VENUS: INTERACTION WITH THE SOLAR WIND), as do other planets and also COMETS (SOLAR WIND: INTERACTION WITH COMETS). Kreutz discovered a family of comets that approach close to the Sun (COMETS: KREUTZ SUNGRAZERS), many of which have been discovered by the LASCO instrument on the SOHO satellite. At the heliopause, the solar wind connects with the rest of the Galaxy (SOLAR WIND: INTERACTION WITH LOCAL INTERSTELLAR MEDIUM).

PLANETARY MAGNETOSPHERES are the magnetized plasma environments of the planets. A range of planets have been studied, including JUPITER: MAGNETOSPHERE and SATURN: MAGNETOSPHERE, as well as MERCURY: MAGNETOSPHERE, URANUS AND NEPTUNE: ATMOSPHERES, IONOSPHERES AND MAGNETOSPHERES. Planetary satellites are of particular interest (SATURN: MAGNETOSPHERE INTERACTION WITH TITAN, MAGNETOSPHERES: JUPITER, SATELLITE INTERACTIONS, MAGNETOSPHERES: JUPITER, RADIO EMISSION, IO: PLASMA TORUS).

The Earth's magnetosphere

Due to its proximity to us, the MAGNETOSPHERE OF EARTH has been extensively studied in great detail and presents an opportunity to understand the behavior of many basic plasma processes. Since the magnetosphere acts as an obstacle to the supermagnetosonic solar wind, a *bow shock* stands in the flow ahead of the Earth (MAGNETOSPHERE OF EARTH: BOW SHOCK). The surface that separates the Earth's magnetic field from the solar wind magnetic field is called the *magnetopause* (MAGNETOSPHERE OF EARTH: MAGNETOPAUSE). Between the bow shock and the magnetopause lies the *magnetosheath*. The Earth's magnetic field is swept downstream by the solar wind to form a long tail (MAGNETOSPHERE OF EARTH: GEOMAGNETIC TAIL), the central and densest part of which is called the *plasma sheet* (MAGNETOSPHERE OF EARTH: PLASMA SHEET). Between the magnetic field that closes on the dayside of the Earth and the tail field that is swept down on the nightside lies the *dayside cusp* (MAGNETOSPHERE OF EARTH: DAYSIDE CUSP).

Within the closed part of the Earth's magnetic field there lie: a *ring current* (MAGNETOSPHERE OF EARTH: RING CURRENT) which flows westward roughly in a circle in the equatorial plane about the Earth; the *radiation belts*, consisting of trapped particles in orbits that circle the Earth from about 1000 km above the surface to about six Earth radii (MAGNETOSPHERE OF EARTH: RADIATION BELTS); a population of cold dense plasma (*plasmasphere*) that coexists with the radiation belts (MAGNETOSPHERE OF EARTH: PLASMASPHERE). Streams of energetic particles impacting the Earth's upper atmosphere in a ring around each of the Earth's poles form the *aurorae* and excite AURORAL KILOMETRIC RADIATION. Within the magnetosphere there is a wide range of waves (MAGNETOSPHERE OF EARTH: WAVES). Also, the rotation of the Earth and the flow of the solar wind cause the plasma and magnetic field lines within the magnetosphere to move in a complex pattern (MAGNETOSPHERE OF EARTH: CONVECTION). Regions of enhanced solar wind flow compress the magnetosphere (MAGNETOSPHERE OF EARTH: GEOMAGNETIC STORMS AND SOLAR WIND ORIGINS) for 1–5 days. *Substorms* occur for 1–3 hours in response to a sustained southward turning of the interplanetary magnetic field, after which the tail of the magnetosphere goes unstable and reconnects (MAGNETOSPHERE OF EARTH: SUBSTORMS). This causes a plasmoid to be formed in the tail and ejected downstream and accelerates fast particles that greatly enhance the aurorae.

Sun as a Star

Observations of the Sun made with instruments on the ground or on satellites in near-Earth orbits have the enormous advantage over corresponding observations of stars in that the Earth–Sun distance is only about 150 000 000 km. Even the nearest star to the Sun (PROXIMA CENTAURI) has a distance which is 271 000 times this amount, while most of the bright stars visible in the night sky are much more distant still. Thus, while ground-based solar telescopes are capable of resolving features on the Sun as small as 150 km across (0.2 arcsec in angular measure), and satellites (in particular the Transition Region and Coronal Explorer or TRACE, launched in 1998) features as small as 725 km (1 arcsec), nothing at all can be resolved on stellar surfaces by conventional means. However, using techniques developed over the years we have been able to deduce the presence of surface and atmospheric features in nearby stars that seem to have their counterparts in the Sun, and so we are able to make deductions about stellar activity along the same lines as we have about solar activity since the time of the first telescopic observations in the early seventeenth century.

Quantities characterizing the Sun as a star

It is important for several purposes to consider certain quantities for the Sun as a star so as to compare with other stars and to use this information as input into the so-called standard model of the solar interior, giving a mathematical description of the way pressure and temperature vary with distance from the center of the Sun. These quantities can be summarized as luminosity, radius, effective temperature, age, chemical composition, mass and rotation rate.

To illustrate, if we know the Sun's luminosity and spectral type (or equivalently the effective temperature), we may place the Sun's position on the familiar HERTZSPRUNG–RUSSELL (HR) DIAGRAM (absolute magnitude versus spectral type) or color–magnitude diagram. The luminosity can be obtained from accurate spacecraft measurements of the solar irradiance (formerly and still occasionally known as the solar constant), i.e. the amount of radiant energy received at the Earth outside its atmosphere per unit area per unit time. There is a small long-term variation in the irradiance with solar cycle and a short-term one, too, depending on the spottedness of the Sun. Broadly, the total variation is 1365 to 1369 W m^{-2} (i.e. peak-to-trough variation of 0.3%). Taking the mean irradiance to be 1367 W m^{-2} and with 1 AU equal to 149 597 900 km, we have for the solar luminosity (i.e. total radiant power in all wavelengths) 3.844×10^{26} W. This is equivalent to an absolute bolometric magnitude (defined by the apparent magnitude at a distance of 10 pc) of +4.72.

The radius (or diameter) of the Sun, i.e. of its photosphere, can be determined in a number of different ways, and there are reasonably precise measurements that date back to the early 1700s. Direct measurements using TRANSIT times of the Sun across the field of a meridian telescope were made for many years (e.g. at the Paris Observatory), and though they are considered fairly reliable there is little doubt that measurements using start and end times of total eclipses of the Sun are the best way of determining the solar diameter. HALLEY's 1715 measurement using this method gave the mean solar diameter as 1920 arcsec (32′ 00″) which is very close to the modern value. Another accurate method of determination involves the transits of Mercury which occur only about 14 times a century. Measurements based on eclipse and Mercury transit methods over the past 300 years indicate a value for the solar diameter of a small fraction of an arcsecond less than 1920 arcseconds, which translates into a linear value for the solar radius of 695 970 km. Despite claims made in the past, the measurements indicate a constant value over this period, and there seems to be a practically zero value for solar oblateness (excess of equatorial over polar diameters).

The Sun's effective temperature, obtained from the solar irradiance and the Stefan–Boltzmann law for a black body, is 5770 K. The equivalent spectral type is G2, luminosity class V (i.e. a main-sequence or non-evolved star). This places the Sun very nearly at the center of the main sequence in the HR diagram when a large variety of stars—very luminous as well as very dim—are plotted. The Sun's color, as defined on the UBV photometric system, is given by $B - V = +0.65$ and $U - B = +0.13$.

The age of a star is an important quantity, as with increasing age a star depletes its hydrogen 'fuel' at its core and eventually evolves off the main sequence. Stellar ages can only be directly determined for members of star clusters, but the Sun's age can be fairly accurately determined from the age of the oldest meteorites discovered on the Earth; latest estimates are 4.6×10^9 years (4.6 Gyr). This is considerably larger than the ages of associations of stars known to be evolving towards or just recently arrived at the main sequence (e.g. ages of O- or T-associations are around 1 Myr) and most open clusters of stars (e.g. the Pleiades cluster's age is 60 Myr, the Hyades 600 Myr). However, the Sun's age is much less than the age of globular clusters (mean about 10 Gyr) and the latest estimates of the age of the universe (12 Gyr).

Again, for stellar evolution purposes, the chemical composition is of great importance. For the Sun, we are able to make very accurate measurements of the fractional amounts of relatively abundant elements in the photosphere because the great amount of light available enables us to get high-resolution visible-light spectra. In broad terms, the composition is 91% H, 9% He, and only 0.1% heavier elements (or 'metals'). The elements C, O, N, Ne and Fe feature as some of the most abundant heavier elements. Despite what would appear to be the small total metal abundance, the Sun is considered to be 'metal-rich' and belongs to POPULATION I (i.e. is a second-generation star). (There is some evidence, though this remains controversial, that the solar corona has enhanced abundances of certain heavy elements, in particular those with a relatively small value of first ionization potential.)

A star's mass determines the nature of its evolution—a large-mass star evolves very fast, a star with small mass settles down to a long existence in the low-luminosity end of the main sequence, while a body with very small mass never achieves stellar status at all, i.e. does not maintain its energy output by nuclear fusion reactions at its core. The Sun's mass can be very precisely determined from planetary motions using KEPLER'S third LAW: the cube of a planet's distance from the Sun divided by the square of its period gives G times the product of the sum of the Sun's and planet's masses. The best estimates for the Sun's mass give 1.989×10^{30} kg. Stellar masses can be directly determined for binary systems, i.e. where the two components are gravitationally bound, in which the orbits can be determined by continued observations over a period of time. By such means, stellar masses from 0.1 to 50 times the solar mass have been found. The Sun's mass, then, is approximately a logarithmic mean of the extremes.

For stars that have ages of 1 Gyr or more, there is an approximate relation between activity (as measured by numbers of active regions or propensity to flare) and rotational rates, defined by equatorial rotation speeds. This is most likely due to the way in which magnetic fields are generated by dynamo action in convective zones (or, for stars like the Sun, the base of convective zones). The Sun rotates with a period that depends on latitude: 25 days at the equator and up to 33.5 days at latitude 80°. The corresponding rotational speed at the equator is 2 km s^{-1}. Main-sequence stars known to be younger than the Sun from their larger rotational speeds are also much more active (with huge flares, many times more energetic than the largest solar flares), while in general stars with smaller rotational speeds have very low or apparently zero levels of flaring.

In summary, the Sun occupies very much an intermediate position in comparison with other stars by almost any measure: mass, radius, luminosity, age, rotation/activity. It lies on the main sequence and is approximately at the midpoint of its life: in another 5 Gyr it will have depleted its hydrogen fuel at its core, and will start to evolve off the main sequence to a red giant phase.

Global oscillations: observing the Sun's interior

With the Sun's proximity to the Earth, we are able to resolve features on its surface under ideal seeing with the best ground-based telescopes that are only 150 km across, corresponding to 0.2 arcsecond. With such a high degree of image quality available, there would seem to be little worth in deliberately degrading the resolution, but for certain studies that is what astronomers sometimes choose to do. Such a study is HELIOSEISMOLOGY. The Sun is now known to have non-radial global oscillations, and these are best studied by integrating the visible light output of the entire solar disk.

The outer regions of the solar interior are convective, and convective motions excite sound waves which travel from the surface towards the interior. As an acoustic or resonance cavity is formed when a sound wave travels between two solid boundaries, with the possibility of standing waves or modes if the distance between two boundaries is a simple multiple of the wavelength, so the solar interior acts as an acoustic cavity. A sound wave that propagates into the interior from the solar surface at an angle travels in an arc. The reason for this is that the wave front (perpendicular to the wave direction) has its deepest part traveling faster than its shallowest part since the sound speed is larger at greater depths where the temperature is larger. The sound wave is therefore refracted until it is directed towards the solar surface again where it produces oscillations which are observable through the Doppler shifts of absorption lines in the photospheric spectrum. Such standing waves are called p modes (p for pressure which is the restoring force for these waves). The degree l of the mode can be defined to be the solar circumference divided by the horizontal wavelength, and small values of l ($l = 0$–4) produce global oscillations which are observable through Doppler shifts in integrated sunlight. Individual oscillation modes have only tiny velocity amplitudes, so highly accurate means of measuring Doppler shifts must be made, and generally over long periods of time.

Measurements of low-l p modes have been made for a number of years with the University of Birmingham (UK) BISON NETWORK and the French IRIS global oscillations network, and since 1995 observations have been made from space with the GOLF instrument aboard SOHO. The observations indicate the presence of several strong peaks in the Fourier spectrum in the region around 3 mHz (corresponding to the familiar 5 min period oscillations). The peaks are closely spaced pairs, which comparison with calculations reveals to be due to modes with l equal to 0 and 2 or 1 and 3. The spacing between the peaks can be directly compared with that predicted by the standard solar model where the agreement has been found to be reasonably satisfactory.

The small velocity amplitudes observed in integrated sunlight that global oscillations give rise to would give little hope that global oscillations would be detectable in other Sun-like stars. However, much effort is being directed in the field of astroseismology, the stellar equivalent of helioseismology. For solar-type stars, we would expect the same behavior that has been found from helioseismological studies, so the measurements are at present only bordering on significant detections of oscillations. However, some other stars appear to show definite signs of global oscillations, in particular rapidly oscillating Ap stars. A major discovery in recent times is that of g mode oscillations in γ Dor stars (g stands for gravitation as the restoring force). The observations of solar g modes are equivocal and there is much debate regarding their validity.

Observing the Sun from a nearby star

When we observe stars from the Earth using either ground-based observatories or spacecraft, we are in general unable to see surface features, though we can deduce

their presence by indirect means. Thus starspots can be detected through a technique called Doppler imaging, which uses the fact that the profile of an absorption line is altered in response to a large enough starspot crossing the star's visible hemisphere as the star rotates. Stellar chromospheres are detectable with visible-wavelength and ultraviolet observations. Cyclical behavior in some stars like the Sun's 11-year cycle has been observed through the Ca II H and K emission line intensities, since the emission cores result from stellar chromospheres which, by analogy with the Sun, show active regions as areas of enhanced emission. Similarly, x-ray observations reveal the presence of coronas, and for active cool dwarf stars especially (dMe and dKe stars: d signifying dwarf and e emission in the Hα line) flares are readily observed in wavelengths ranging from m-wave radio to x-rays.

With the Sun, ground-based and spacecraft observations give us a highly detailed view of not only surface features but of the atmospheric structure, and we find the general rise in temperature, above the temperature minimum region (about 500 km above the surface, defined by the optical depth at 500 nm, τ_{500} equal to unity), going up through the chromosphere to the corona. If we were to observe the Sun from a distance of 1.3 pc, the distance of the nearest star Proxima Centauri, we would find evidence for the Sun's atmospheric structure much more difficult to deduce. Whereas for flare stars of type dMe or dKe, and even for M dwarfs as a whole, the emission profiles of the Ca II H and K lines are very obvious, in integrated sunlight the emission peaks are scarcely visible at all, so it is only with high-resolution spectroscopy that the solar chromosphere would be detectable at visible wavelengths. However, ultraviolet observations of the Sun from a nearby star might detect the presence of the chromosphere through the Lyman-α and Mg II lines (121.5 nm and 280 nm respectively). The SOLAR TRANSITION REGION (supposed boundary layer between the chromosphere and corona but possibly due to unresolved structures in the Sun) has a temperature of about 10^5 K, very near the maximum emissivity of lines such as the C IV doublet at 155.0 nm. Again, ultraviolet observations with a spacecraft similar to the International Ultraviolet Explorer (IUE) would only just detect this region. The total x-ray luminosity of the solar corona is about 10^{20} W, a value which is at the lower end of the range of x-ray coronal luminosities detected by the ROSAT spacecraft.

Doppler imaging shows that starspots on RS CVn stars in particular can attain huge dimensions, often a substantial fraction of the star's total surface area. Thus, there are perceptible effects both in total brightness and in the profiles of absorption lines. Some very large sunspots are as much as 100 000 km across, many times the Earth's diameter, but even so not more than about 1% of the Sun's area is covered with spots at any one time. Thus, an observer at the distance of even the nearest star with instruments comparable to those in use at present would probably not be able to detect any light modulations or changes in line profile.

SOLAR PROMINENCES are tongues of cool gas (temperatures typical of the chromosphere, about 10^4 K) located in the solar corona. They are most often seen in Hα light, in emission off the limb or in absorption on the solar disk (when they are known as FILAMENTS) and may take on enormous proportions (such as the famous 'Anteater' prominence in June 1946). Their counterparts have often been seen in some active stars, in particular through changes in the profile of the Hα line as the prominence crosses the visible hemisphere of a rapidly rotating star such as AB Dor (dKe). Again, these stellar prominences seem to have much greater dimensions than solar prominences, and in the case of AB Dor are 'co-rotating' with the star's photosphere, with distances from the star of up to 9 stellar radii. Solar prominences are much too small and tenuous to have any perceptible effect on the profile of the Hα line as observed from a great distance.

The flares that are seen on dMe stars and the interacting binaries of the RS CVn type are truly enormous compared with even the largest observed on the Sun. Much of the radiated energy of stellar or solar flares appears in the x-ray region. Energies of up to 10^{29} J have been observed on RS CVn binaries, and up to 10^{27} J in the case of dMe stars. This compares with only about 3×10^{24} J for the largest solar x-ray flare ever observed. In fact, although solar flares give rise to an enormous increase in x-ray emission on occasions, the total energy output of the Sun completely overpowers any flare: the energy output is increased by no more than 0.001%. The only way a flare could be detectable from a great distance would be in the x-ray region, since there would be a negligible effect on the Hα or other line profile and the total visible light output.

Sun: Basic Properties

The standard star

The Sun is a gaseous sphere in hydrostatic equilibrium. It emits light because it is hotter than the surrounding space. Such a brief characterization is true for most other stars as well. The distinction of the Sun is its close vicinity to the Earth, so that it is the only star where we can see fine details on the surface (see SOLAR PHOTOSPHERE). Examples are the granulation as well as other manifestations of convective energy transport, dark spots that are particularly structured in their umbrae and penumbrae, or limb prominences that are supported by an appropriate magnetic field. It is true that, by indirect methods, similar phenomena have been inferred for stellar surfaces, but the interpretation of the observations would be difficult, if not impossible, without the solar evidence (see SOLAR–STELLAR CONNECTION).

A particular example of solar uniqueness is that the Sun is the only star in equilibrium whose neutrino luminosity has been measured. From celestial sources other than the Sun, only some 19 neutrinos were detected on 23 February 1987 after the explosion of supernova 1987A in the Large Magellanic Cloud.

Fundamental quantities

In order to determine the most fundamental solar quantities one needs to know the *distance* of the Sun from the Earth. The mean distance, or *astronomical unit*, is

$$A = 149\,597\,870 \pm 2 \text{ km}.$$

This value is the mean distance between the centers of the Sun and the Earth. The 'mean' is over the *eccentric anomaly*, i.e. the angle between the Sun–Earth line and the direction to the perihelion of the elliptical orbit. The most accurate measurement of A is obtained from radar echos within the solar system, and from Kepler's third law. The uncertainty arises from the uncertainty of the radar echos, which yield the *light time for unit distance*, $\tau_A = 499.004\,782 \pm 0.000\,006$ s.

The following is a list of some fundamental solar quantities:

Mass, $m_\odot = (1.9889 \pm 0.0003) \times 10^{30}$ kg

Radius, $r_\odot = (6.960 \pm 0.001) \times 10^8$ m

Luminosity, $L_\odot = (3.844 \pm 0.010) \times 10^{26}$ W

Age, $t_\odot = (4.57 \pm 0.05) \times 10^9$ years

Base of convection zone, $r_{CZ} = (0.713 \pm 0.003) r_\odot$.

The chemical composition at the surface, by fractions of mass, is

Hydrogen, $X_S = 0.734 \pm 0.005$

Helium, $Y_S = 0.248 \pm 0.005$

Other elements, $Z_S = 0.018 \pm 0.002$.

Several remarks concerning these values must be made, in particular with respect to the error estimates.

Mass

Time and distance measurements, and the application of celestial mechanics, yield the *product*, $Gm_\odot = (132\,712\,438 \pm 5) \times 10^{12}$ m^3 s^{-2} of the solar mass with the general constant of gravitation. The uncertainty of $m_\odot$ rises entirely from the uncertainty of $G = (6.672\,59 \pm 0.000\,85) \times 10^{-11}$ m^3 kg^{-1} s^{-2}.

Radius

In a photoelectric measurement the value of $r_\odot$ can be derived from the angular distance between the two inflection points of an intensity profile across the visible solar disk. Recent experiments yield values around 959.6″ for the angular semi-diameter, remarkably close to visual heliometer measurements carried out in the nineteenth century (which led to the value 959.63″ used in the *Astronomical Almanac* until today). The statistical errors of some of the individual experiments are as small as 0.01″. However, the systematic uncertainty must be at least 0.1″, as is evident from the spread of the results. The more conservative error given above accounts for this.

The solar limb defined by the intensity inflection point is ≈300 km above the level where the optical depth is $\tau = 2/3$. For a boundary condition to a solar interior model, applied at that level, the radius is therefore $r = (6.957 \pm 0.001) \times 10^8$ m. A comparison of theoretical and observed frequencies of solar f-mode oscillations confirms this value of the radius at $\tau = 2/3$.

Luminosity

The Earth's atmosphere absorbs or reflects a considerable fraction of the solar radiation. Hence an accurate measurement can only be made from space. Figure 1 shows the total solar irradiance obtained from bolometric experiments on balloons, rockets and satellites since 1978. Short-term as well as long-term *relative* variations, measured by the diverse experiments, agree very well with each other, thus demonstrating their solar origin. Most conspicuous is a variation with the 11-year activity cycle of the Sun. This variation is *in phase* with the cycle: the maxima of irradiance and of the number of sunspots coincide. The amplitude of the variation is ≈0.09%, peak-to-peak. The occurrence of *solar faculae* depends on the cycle phase (and on heliographic latitude) and plays the major role in models of this variation.

Figure 1 also demonstrates differences of several W m^{-2} between the *absolute* results of the diverse experiments, indicating systematic uncertainties. The solar luminosity given in the present list is $4\pi A^2$ times the mean irradiance value 1367 W m^{-2} measured by the 'Active Cavity Radiometer Irradiance Monitoring I' instrument on the Solar Maximum Mission. This instrument had a precise solar pointing system and, by the use of *three* absorbing cavities operating at different intervals, it had the capability to correct for detector degradation; its accuracy has been estimated to ±0.2%. The error of $L_\odot$ given above is a conservative guess based on this number (see SOLAR IRRADIANCE).

Age

The decay of long-lived radioactive isotopes, notably ^{238}U, ^{235}U, ^{232}Th, ^{40}K, ^{87}Rb, ^{147}Sm and ^{187}Re, yields the *age of meteorites*, defined as the time between the melting, i.e. homogenization of isotopes, and subsequent crystallization of these objects, and the present. Such age determinations are possible with errors as small as a few million years. Nevertheless, there is a larger uncertainty in the solar age because of the uncertainty in the state of the Sun's evolution at the time of meteorite formation. Both the initial collapse of an interstellar cloud and the final hydrostatic contraction towards the main sequence in the Hertzsprung–Russell diagram have time scales of order 10^7 years, which leads to the uncertainty estimate of $t_\odot$ (see SOLAR EVOLUTION).

Depth of convection zone

The best value of r_{CZ} is obtained by means of helioseismology. The frequencies of the Sun's acoustic modes of oscillation (the p modes) depend on the gradient, dc/dr, of the sound speed, and therefore on the gradient of the temperature. The temperature gradient makes a characteristic transition from the nearly isentropic stratification in the convection zone to the core stratification that is determined by the radiative transport of energy. The error estimate of r_{CZ} reflects the uncertainty of the inversion of the observed p-mode frequencies, and (possibly) an uncertainty in the knowledge of the thermodynamic state in the Sun (see SOLAR INTERIOR: CONVECTION ZONE).

Chemical composition at the surface

Helioseismology yields the most precise determination of the abundance of helium. Since He is an abundant element in the Sun, its ionization energy substantially contributes—in a zone of partial ionization—to the specific heat and hence to the adiabatic exponent and the speed of sound. Therefore, the measurement of p-mode

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

frequencies can be used to determine the helium content. The result listed above pertains to the outer solar layer between r_{CZ} and $r_\odot$ which is permanently mixed by turbulent convection. The uncertainty corresponds to the uncertainty of the frequency inversion and of the thermodynamic state in the layer of partial ionization of helium.

The heavy element mass fraction, Z_S, is determined essentially from a spectroscopic analysis of the solar photosphere, and from abundance ratios found elsewhere in the solar system. The uncertainty is essentially due to the errors of the spectroscopic results (see SOLAR ABUNDANCES).

Internal constitution

The internal structure of the Sun is governed by the hydrostatic support of the solar mass, the conversion of nuclear into thermal energy by fusion of hydrogen into helium, and by the mechanisms of radiative and convective energy transport. The thermodynamic state of the solar interior is close to the state of a perfect gas; small deviations of the perfect gas law occur near the solar center where partially degenerate electrons contribute ≈1.5% to the pressure, as well as in the outer part—mainly in the envelope where the temperature is below 2×10^5 K and where excitation and ionization of neutral or partially ionized species make a contribution of up to a few per cent.

In addition to the equation of state, the *opacity*, defined as the mean absorption coefficient κ (i.e. properly averaged over the photon frequency), plays a major role in our knowledge of the stellar interior. It is derived through a detailed analysis of the diverse atomic processes that absorb or scatter photons. For the Sun, generally opacity *tables* are used, which list κ as a function of temperature, density and chemical composition. The most recent tables (the 'OPAL' tables) have been calculated at the Lawrence Livermore National Laboratory (USA). The opacity is of crucial importance for the temperature profile in the solar core below r_{CZ}, where energy is transported by radiation; it also is crucial in determining the depth where radiative transport becomes inefficient and, therefore, the stratification becomes unstable to convection. For the solar interior the opacity is still a source of some uncertainty; for example, the depth of the convection zone in calculated models has changed with the incorporation of new opacity tables, and only the recent Livermore tables yield models having a r_{CZ} in close agreement with the helioseismological result (see SOLAR INTERIOR: EQUATION OF STATE AND OPACITY).

Over the Sun's age the helium content in the central region has increased, mainly by *fusion of hydrogen*, and—by a smaller amount—by *gravitational settling*. Evolutionary calculations show that gravitational settling has reduced the helium content of the convective solar envelope from an initial mass fraction $Y_{ini} \approx 0.280$ to the present value $Y_S \approx 0.248$. For the elements heavier than helium, settling is the only mechanism of chemical differentiation. The change in the envelope is from an original $Z_{ini} \approx 0.020$ to the present value $Z_S \approx 0.018$.

The *Standard Solar Model* is based on the best available physical and chemical input, as outlined in this section. This Standard Model reproduces, within some uncertainties, the observed basic properties of the Sun—with one exception, the neutrino luminosity (see below). At the solar center, some of the physical quantities are as follows:

Temperature, $T_C = 1.57 \times 10^7$ K
Density, $\rho_C = 1.52 \times 10^5$ kg m^{-3}
Pressure, $P_C = 2.37 \times 10^{16}$ Pa
H mass fraction, $X_C = 0.34$
He mass fraction, $Y_C = 0.64$
(see SOLAR INTERIOR: STANDARD MODELS).

The neutrino discrepancy

Nuclear energy conversion in the solar interior is directly confirmed by the measurement of solar neutrinos. However, the observational result quantitatively falls short with respect to the prediction based on the Standard Solar Model. Radiochemical experiments that use neutrino capture by the chlorine and gallium isotopes ^{37}Cl and ^{71}Ga yield ≈28% and ≈55% respectively of the theoretical expectation. Water Cerenkov detectors that record neutrino–electron scattering have demonstrated that the neutrinos arrive from the direction of the Sun; their yield is slightly less than 50% of the theoretical value.

The Standard Solar Model predicts not only the total neutrino flux from the Sun, but also its energy distribution. The diverse experiments are sensitive to different ranges of neutrino energy. Although the predicted energy distribution may be modified, in particular by the construction of a solar model with a lower central temperature, it has not been possible to calculate models whose neutrino production would be in accord with all the observational results simultaneously. Moreover, the means to change the model temperature (opacity, equation of state, nuclear reaction rates) are rather limited. It therefore appears that the discrepancy cannot be resolved in the astrophysical context. Instead, physical concepts that lie beyond the standard electroweak model of elementary particles may be required (see SOLAR INTERIOR: NEUTRINOS).

Oscillations and helioseismology

The Sun supports two kinds of oscillation around its hydrostatic equilibrium stratification. According to their predominant restoring forces, these oscillations are classified as pressure or p modes, and gravity or g modes. The spherically symmetric p-mode oscillation has a fundamental period of ≈63 min. This fundamental mode as well as the first few overtone modes have not yet been observed. But the frequencies of numerous higher overtones, with periods in the range of 2 to 20 min, have been measured, for spherically symmetric as well as for asymmetric, or non-radial, p modes. The non-radial modes are characterized by their spherical harmonic

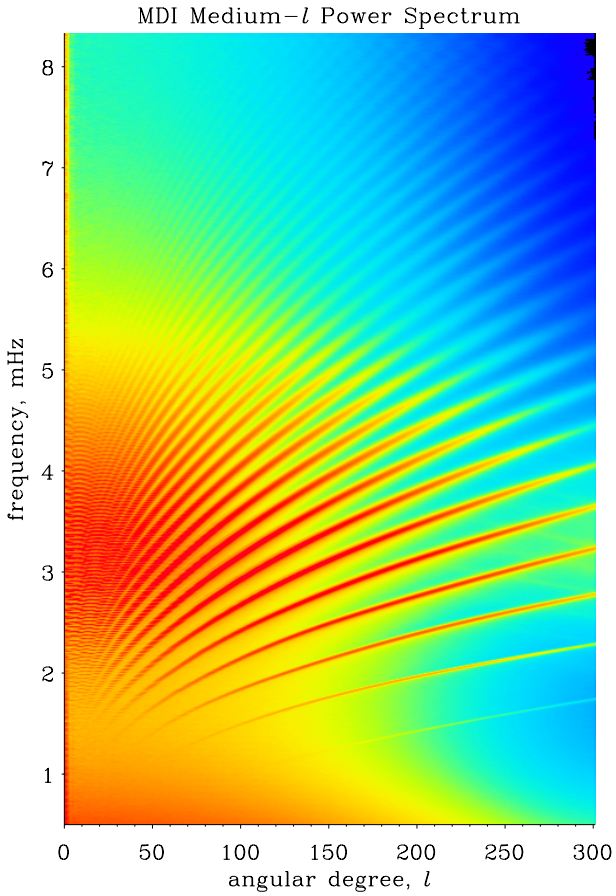

Figure 2. Power distribution of observed solar p modes in the degree–frequency space. (Data from the Michelson Doppler Imager on SOHO, cf Kosovichev *et al* (1997).)

degree l; oscillations with degrees up to $l \approx 4000$ have been found. In the degree–frequency diagram the p modes are aligned along well-defined ridges, as shown in figure 2 (see SOLAR INTERIOR: LOCAL HELIOSEISMOLOGY).

The solar p-mode frequencies are currently determined with a relative error of less than 10^{-3}, for some less than 10^{-4}. Theoretical eigenfrequencies of the Standard Solar Model are calculated with equal accuracy. However, the relative deviations between measured and calculated frequencies have reached 10^{-3}–10^{-2} for some of the theoretical solar models; such deviations have therefore been used to refine the physical input to the model. Modifications in the equation of state, more accurate abundances of chemical elements, more detailed atomic physics for the calculation of opacity tables, and the process of gravitational settling of helium and the heavier elements have thus been incorporated into the Standard Solar Model.

There is no firm evidence for the existence of g modes on the Sun, in spite of considerable observational effort.

Solar rotation

The rotation of the Sun has been known since about 1610 when Galileo Galilei and other astronomers began to use the newly invented telescope for regular observations of sunspots. From such observations R C Carrington by 1863 had derived the *rotation elements*, i.e. the two angles that define the direction of the Sun's axis of rotation. These angles are the inclination, $i = 7.25^\circ$, of the axis with respect to the normal on the ecliptic plane, and the longitude of the ascending node, $☊ = 75.73^\circ$ (for 1998), measured in the ecliptic plane from the equinox direction. Due to the precession of the Earth's axis the equinox direction recedes by $50.26''$ per year; ☊ increases at the same rate, because the direction of the Sun's axis remains fixed. The rotation elements determined by Carrington are still used in the *Astronomical Almanac*, although modern evaluations of long-term sunspot observations yield a slightly steeper axis, with $i \approx 7.13^\circ$. Carrington's ☊ agrees with the modern result.

From the transit of sunspots across the solar disc Carrington derived a mean synodic period of rotation, namely 27.2753 days. Time intervals of this length are counted as *Carrington rotations*, with rotation no 1 starting on 9 November 1853. The synodic mean angular velocity corresponding to the Carrington rotation is $\Omega_{\rm syn} = 2.67 \times 10^{-6}\ {\rm s}^{-1}$; the sidereal mean value is $\Omega_{\rm sid} = 2.87 \times 10^{-6}\ {\rm s}^{-1}$.

Due to the rotation the figure of the Sun is slightly oblate. The difference between the equatorial and polar radii, $r_{\rm eq} - r_{\rm pole} \approx 10^{-5} r_\odot$, has been measured in a number of experiments (see SOLAR INTERIOR: SOLAR DIAMETER, OBLATENESS AND TEMPERATURE).

The solar rotation is non-uniform, i.e. the angular velocity $\Omega(r, \theta)$ depends on radius r and colatitude θ. At the surface, the θ-dependence is directly observed, both by means of tracers such as sunspots and spectroscopically. Spectroscopic data from Mount Wilson Observatory yield $\Omega_{\rm sid}(r_\odot, \pi/2) = 2.84 \times 10^{-6}\ {\rm s}^{-1}$ at the equator and $\Omega_{\rm sid}(r_\odot, 0) = 2.01 \times 10^{-6}\ {\rm s}^{-1}$ at the poles. Sunspots as tracers generally yield a slightly faster rotation, although they can only be used at low latitude, up to about $\pm 40^\circ$.

Below the surface the Sun's rate of rotation has been determined by helioseismology. Non-radial p modes of degree l have a $(2l + 1)$-fold degeneracy in the case of spherical symmetry. Rotation breaks this symmetry and removes the degeneracy. The frequencies are split into $(2l+1)$-fold multiplets. Since different modes of oscillation penetrate into different depths of the Sun, the frequency splitting can be inverted; the angular velocity as a function of r can thus be obtained. Moreover, multiplets with non-equidistant frequency spacing carry information about the dependence of Ω on latitude.

The helioseismological results (figure 3) demonstrate that, within the convection zone, the angular velocity has approximately the same latitude dependence as at the surface. At the base of the convection zone, around $r = 0.7 r_\odot$, there is a transition region of thickness $\Delta r \approx 0.1 r_\odot$ to a core with approximate solid-body rotation; in the core the angular velocity is of the same order as around $\pm 30^\circ$ latitude at the surface (see SOLAR INTERIOR: ROTATION).

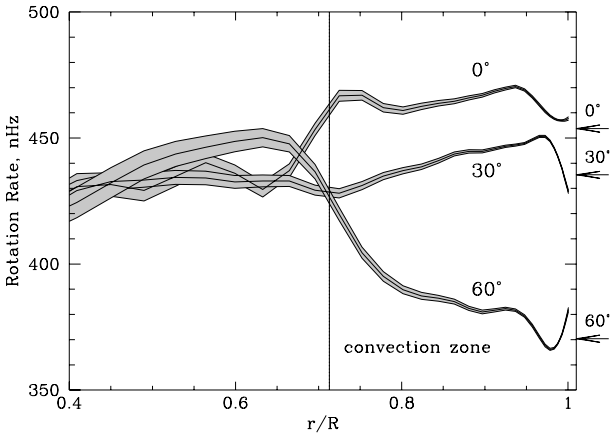

Figure 3. Solar rotation rate, as a function of r, for three heliographic latitudes; an inversion of data obtained with the Michelson Doppler Imager on SOHO. The vertical line marks the base of the convection zone; the arrows indicate the rotation rate measured spectroscopically at the surface. (From Kosovichev *et al* (1997).)

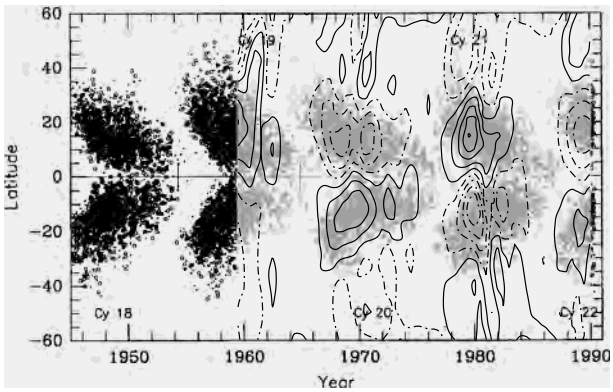

Figure 4. Butterfly diagram of sunspots (dark areas), and contours of the radial component of the mean poloidal magnetic field (solid positive, dashed negative).

The magnetic field of the Sun

Zeeman splitting of spectral lines in sunspots was first reported by G E Hale in 1908. The magnetic field in the spots that accounts for the splitting has a field strength of 0.2–0.3 T. Sunspots preferentially appear in pairs of opposite magnetic polarity, oriented in the heliographic longitude direction, with the leading spot (in the sense of solar rotation) slightly closer to the equator. The orientation is the same for all pairs within each hemisphere and each 11-year sunspot cycle, but reverses from one cycle to the next and is antisymmetric with respect to the equator (*Hale's rules*). The full magnetic cycle therefore lasts 22 years (see SOLAR CYCLE).

The magnetic field of the sunspots has its origin in the solar interior, where it is generated by a self-excited magneto-hydrodynamic dynamo. The seat of this dynamo most probably is the transition region at the base of the convection zone, around $r = 0.7r_\odot$. At this depth the shearing non-uniform rotation (figure 3) generates a toroidal magnetic field from a pre-existing poloidal field. If in a tube of magnetic flux the field strength reaches a critical value of order 10 T, the tube may become unstable, with loops rising to the solar surface. By this process bipolar magnetic regions and pairs of sunspots are formed (see SUNSPOTS).

Individual sunspots have a lifetime of days to months. At the begin of each 11-year half-cycle, spots form at intermediate heliographic latitude, around $\pm 35^\circ$. In the course of the cycle the two zones of sunspot emergence migrate toward the solar equator. This is known as the 'butterfly diagram', cf figure 4. The cause of the migration is closely related to the solar dynamo. The mechanism is modeled in particular in terms of the $\alpha\Omega$-dynamo. In this model the non-uniform rotation is complemented by the interaction of the Coriolis force with loops of magnetized material; a new (reversed) parent poloidal field for the generation of the toroidal field of the next cycle is formed in this way. Figure 4 contains mean contours of the measured poloidal field (see DYNAMO THEORY).

Outside the sunspots, and also outside the latitude zones populated by sunspots, the solar magnetic field appears in the form of locally concentrated flux tubes. These tubes are too small to cause dark spots, and generally also too small to be resolved in observed magnetograms. But their field strength may reach 0.2 T and, because they are so numerous, their total absolute magnetic flux is comparable to the flux that is concentrated in sunspots (see SOLAR MAGNETIC FIELD).

The outer atmosphere and heliosphere

The outer atmosphere of the Sun consists of the *chromosphere*, with a mean height of about 2000 km, the *transition region*, where the temperature rapidly changes from $\approx 10^4$ K to $\approx 10^6$ K, and the *corona*, which has a temperature above 10^6 K and extends over several solar radii. Because of its high temperature, the corona expands with a velocity that increases outwards. At a critical distance r_c, probably between $5r_\odot$ and $10r_\odot$, the expansion becomes supersonic and turns into the *solar wind*. At the Earth's orbit the wind velocity varies between 300 and 700 km s^{-1}. At a distance of the order of 50 astronomical units, according to theory, a shock marks the transition to the interstellar medium. There the dynamic pressure of the solar wind matches the interstellar gas pressure (see SOLAR WIND: GLOBAL PROPERTIES). The diverse regions of the outer solar atmosphere are not horizontally uniform layers, but rather highly structured. The agent that dominates the structure is the magnetic field. The ratio of gas pressure to magnetic pressure (the plasma β) is small, in contrast to the solar interior where $\beta > 1$. The main elements of the structure are spicules and prominences in the chromosphere; arches, streamers and coronal holes in the corona; and low- and high-speed streams in the solar wind. The interaction of the magnetic field with the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

solar wind also leads to breaking of the Sun's rotation: the field acts as a lever arm, reaching outwards to the *Alfvén radius* r_A where the magnetic and kinetic energy densities become equal. The Alfvén radius should lie between 10 and 15 solar radii; its position has not yet been determined experimentally (nor has the position of r_c), because no spacecraft has yet approached the Sun closer than 0.29 astronomical units.

In addition to the spatial inhomogeneity, the outer atmosphere is highly variable in time. As the inhomogeneity, the variability is due to the magnetic field. Magnetically stored energy is set free by instabilities, magnetic lines of force reconnect and accelerate particles. Chromospheric flares, bursts of radio emission and coronal mass ejections follow (see SOLAR ACTIVE REGIONS).

Sun: Safe Observation

Generally speaking, astronomy is a fairly safe pastime. There is, however, one celestial object which is highly dangerous: the SUN. Even the solar surface is at a temperature of well over 5000 °C, and deep at the core the temperature rises to around 15 000 000 °C; remember, the Sun may be regarded as a vast nuclear reactor.

Staring straight at the Sun, even with the naked eye alone, is emphatically not to be recommended. The human eye is delicate, and all too easily damaged; safety considerations must always be paramount—as many people in the past have found to their cost. Carelessness can result in permanent eye damage, or even blindness. Therefore let us consider what the dangers are, and what precautions need to be taken.

With the naked eye, a suitably dark filter is safe enough, but it must be really dense. Welding glass is to be recommended, at least Grade 14, and is easy to obtain. There are occasions when sunspot groups become large enough to be seen in this way, but it is best to wait until the Sun is low down in the sky, preferably shining through a certain amount of mist or haze.

Fully developed, fogged black and white film has often been used, but some modern films are not completely effective, and so are best avoided. Exposed color film should never be used, because it is no barrier to infrared radiation which is dangerous to the eye.

Smoked glass is often recommended, but is not safe. By its very nature, the deposit is uneven, and any pinprick already present or caused by fingering produces what may be termed a 'pinhole camera' which will focus onto the observer's eye.

Much the best filter is Mylar, which is a very tough proprietary plastic film a few microns thick. For solar work, filters are made by coating the film with a very thin layer of aluminum. If the filter is to be used with the naked eye alone, then Mylar coated on both sides is best; for photography single-sided coating is better, because it means that exposure times can be shorter. It must never be confused with 'silver paper', which is a very thin sheet of aluminum, and provides virtually no protection at all.

The only danger with Mylar comes from pinholes. Before using the filter, check it carefully, and if there are any pinholes throw the filter away.

Always remember that the Sun is more dangerous than it often looks. Low down, shining through thick horizon haze, it seems deceptively mild and harmless. The temptation then is to take a quick direct look with binoculars or a telescope. Eye damage is virtually certain to result, and there have, unfortunately, been many cases of people who have been blinded in this way.

Remember, too, that we are not dealing only with visual light. The Sun is also very powerful in the ultraviolet and infrared wavelengths. If you want to demonstrate the heating involved, simply hold up a magnifying glass and focus the Sun's rays onto a piece of paper. It does not take long for the paper to become hot, and if the Sun is high in the sky the paper will quickly burst into flame (this was, of course, the way in which Boy Scouts used to light a camp-fire). It does not take much imagination to realize what would happen if this heat were focused onto your eye.

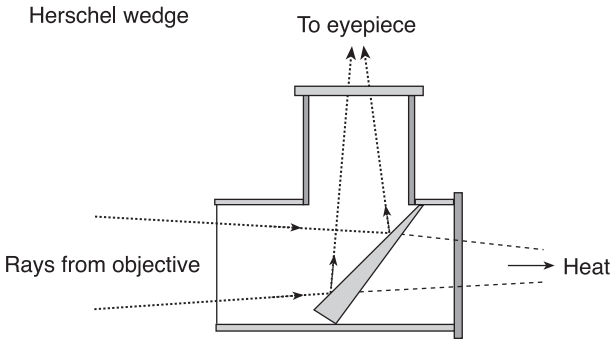

Figure 1.

We come next to observing the Sun with a telescope (binoculars will be discussed below). It is unfortunate that some small telescopes, usually (not always) REFRACTORS, are sold together with dark sun-caps. The instructions claim that it is then safe to fit the sun-cap over the telescope eyepiece, and look direct. This is not true. Such a procedure is appallingly dangerous. Dark caps supplied with small, cheap telescopes are almost always of inferior quality, so that they will not give adequate protection, and they are always liable to crack or shatter without warning, in which case an observer will not have sufficient time to move their eye out of the way. There is an extra hazard, too. Some small telescopes are supplied with 'moon-caps', designed to cut down the glare of the full Moon. So far as the Moon is concerned this is safe enough, because the Moon sends us only a tiny amount of heat, but it is only too easy to confuse a moon-cap with a sun-cap.

There is, however, an easy way to look at SUNSPOTS: use the telescope as a projector.

First, aim the telescope at the Sun, without putting your eye anywhere near the eyepiece; this is easy enough by throwing the telescope shadow on to a screen held or fastened behind the eyepiece. The Sun's disk will then be projected onto the screen, and any spot-groups or FACULAE which happen to be present will be clearly seen; adjust the focus of the telescope until the image is sharp. Adjust the distance of the screen until the projected disk is of the required size (7–8 cm is a good compromise). You can then make a sketch of the disk at your leisure.

Of course, simply holding the screen is awkward, because it means that the observer ideally needs three hands, but to fix a mounting is very easy. It is also very useful to fix a screen over the telescope itself, to cast a shadow and allow only the light from the telescope to pass through.

Detailed views of sunspots can be obtained in this way; of course different magnifications can be used—low

powers for general disk drawings, higher powers for more elaborate sketches of sunspot groups. The Sun rotates in a period of around 27 days, so that a spot will be carried across the disk from one side to the other until it vanishes over the limb; it will reappear at the opposite limb just under 14 days later—unless, of course, it has disappeared in the meantime! Many spot-groups have short lifetimes, though others persist for several revolutions.

The Sun has a cycle of activity with a mean period of about 11 years. At solar minimum the disk may be blank for many consecutive days, while at maximum many spot-groups may be visible at the same time. The next maximum is due around 2000–2001. *Faculae* (Latin, 'torches') are clouds of incandescent gas lying above the brilliant surface; they are easily seen by projecting the image with a small telescope.

Generally speaking, refractors are to be preferred for visual observations of the Sun; with a REFLECTOR there is always the danger of damaging the secondary mirror. Also, with a telescope more than 10 cm in aperture it is usually a good idea to stop down the mirror or object-glass. After all, with the Sun there is plenty of light to spare!

It is possible to use binoculars as projectors, in the same way as a telescope, and sunspots can sometimes be seen in this way, though it is never at all satisfactory.

There are only two sensible ways for direct telescopic viewing of the Sun. One is to use a Mylar filter placed over the object-glass, or upper end of the tube for a reflector such as a Maksutov. Again, exercise the greatest care, and make absolutely certain that the Mylar is undamaged.

The second method is to use a Herschel wedge. This is made up of a fitting for the telescope draw-tube, a partially reflecting surface, and a fitting for the eyepiece (see figure 1). The Sun's light passed through the eyepiece comes from the top surface of a plain glass wedge, while the heat, concentrated by the object-glass or mirror, is passed straight through the open end. The glass is wedge-shaped so that the secondary reflection from its back surface is not also passed up to the eyepiece—if it were, it would produce a double image. When using a Herschel wedge, also add a dark filter, and remember that infrared radiation must be taken into account as well as visible light.

There are various other points to be borne in mind. If you use a telescope to project the Sun's image, remember that the heat on the eyepiece may damage it, particularly if it is often used in this way—so put aside a special eyepiece for the purpose. Remember also to cap the telescope finder. One very famous scholar remembered that on one occasion he forgot to do this and suddenly realized that his beard had caught fire; the finder telescope had focused the Sun's heat in just that position!

Sunspots can be photographed with an ordinary camera equipped with a telephoto lens. Always bear in mind that a camera involves a lens system, and therefore never look through the viewfinder to make sure that the Sun is properly placed; and always use a Mylar filter over the camera lens. Otherwise, the only method is to project the Sun's image on to a screen, in the usual way, and then photograph the screen, but this is not very convenient, simply because the telescope itself is bound to get in the way.

ECLIPSES of the Sun are fascinating; total eclipses are spectacular by any standards—it has been said that a total solar eclipse is the grandest sight in all Nature. As soon as the last segment of the brilliant photosphere has been covered by the disk of the Moon, the Sun's chromosphere flashes into view, together with the CORONA and any PROMINENCES which happen to be present. Because the Moon's shadow is only just long enough to reach the Earth, total eclipses as seen from any one locality are rare (the English eclipse of August 1999 will not be followed by another until 23 September 2090). Partial eclipses are much more common. There are also annular eclipses, when the Moon is in the far part of its orbit and does not appear large enough to cover the Sun completely; a ring of sunlight is left showing round the dark mass of the Moon (Latin *annulus*, a ring).

During totality it is quite safe to look straight at the Sun, with the naked eye, binoculars or a telescope. But—and this cannot be too strongly emphasized—the photosphere must be completely covered. The slightest sliver of the brilliant solar disk is just as dangerous as the uneclipsed Sun. Therefore, the procedure for the eclipse photographer is to take the Mylar filter away only when the corona is first seen, and replace it as soon as the 'DIAMOND RING' effect heralds the end of totality. During partial and annular eclipses, of course, follow the same procedure as with the uneclipsed Sun.

The notes given here apply to the observer who is anxious to follow sunspots, faculae and any eclipses which may be visible, but of course serious solar observers need specialized equipment. Spectrohelioscopes and spectroheliographs are rare in amateur hands, but Hα filters are not; these cut out all the light except that of hydrogen, and once they are in place direct viewing is safe. However, the observer who has acquired equipment of this kind will need no reminder of the dangers involved in solar work.

To sum up, therefore:

(a) The Sun is dangerous, because of its brilliance, its heat and its 'invisible' radiation (ultraviolet and infrared).
(b) With the naked eye, never look straight at the Sun for more than a second or two, and preferably not at all, unless you hold up a dark filter.
(c) Welding-glass gives good protection, and so does exposed, fogged black-and-white film. Exposed color film does not, and also avoid materials such as silver paper.
(d) With a telescope, never use the dark sun-caps so often supplied with small, cheap instruments. Ensure that your filter is perfect and sufficiently dark; Mylar is much the best material.
(e) A Herschel wedge may be used, but add a dark filter to reduce the level of illumination still further. The

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

filter should preferably be of the type which blocks infrared radiation.

(f) Never point a camera straight at the Sun and look through the viewfinder, unless an adequate filter is used.

(g) Remember that the Sun is dangerous even when low down and shining through haze or mist. The temptation to take 'one quick look' through binoculars or a telescope which is not fitted with a proper filter may well have tragic results.

(h) Serious solar observers use equipment such as Hα filters, but they will by that time be aware of any risks.

It is true that some astronomers have been accused of being paranoid about the dangers of solar work. Yet remember that you have only one pair of eyes—and a single mistake will be one too many. A cat may look at a king, but nobody should look unprotected at the brilliant disk of the Sun.

Sundial

One of three types of timekeeping device based on the shadow cast by any fixed vertical object. As the day progresses, the Sun moves across the sky, causing the shadow of the object to move. Depending on the type of device, the object measures apparent solar time with some accuracy.

From about 3500 BC the first device was probably a vertical stick known as a gnomon. By the eighth century BC, more precise devices were in use in Egypt. One example has a base inscribed with a scale of six time divisions fixed in an east–west direction. The design is still in use in some parts of Egypt. Around 300 BC the hemispherical sundial or hemicycle is evident. It was made of a cubical block of stone or wood with a hemispherical opening cut into it. A pointer was fixed at the center of the opening. The path traveled by the shadow of the pointer was, approximately, a circular arc, which varied according to the seasons. These variations were inscribed on the internal surface of the hemisphere and each was divided into twelve equal divisions or hours. Because the length of the day varied according to the season, these hours also varied in length from season to season and even from day to day and were consequently known as temporary hours. There are records of the dial still being used during the tenth century.

The Greeks developed and constructed very sophisticated sundials. One version used the surface of a conic section for greater accuracy. The Romans also used sundials with temporary hours. The Arabs attached much importance to sundials and derived the principles and design from the Greeks. They increased the variety of designs available and, at the same time, simplified the processes of design and construction by using the principles of trigonometry. With the advent of mechanical clocks in the early fourteenth century, sundials with equal hours gradually came into general use.

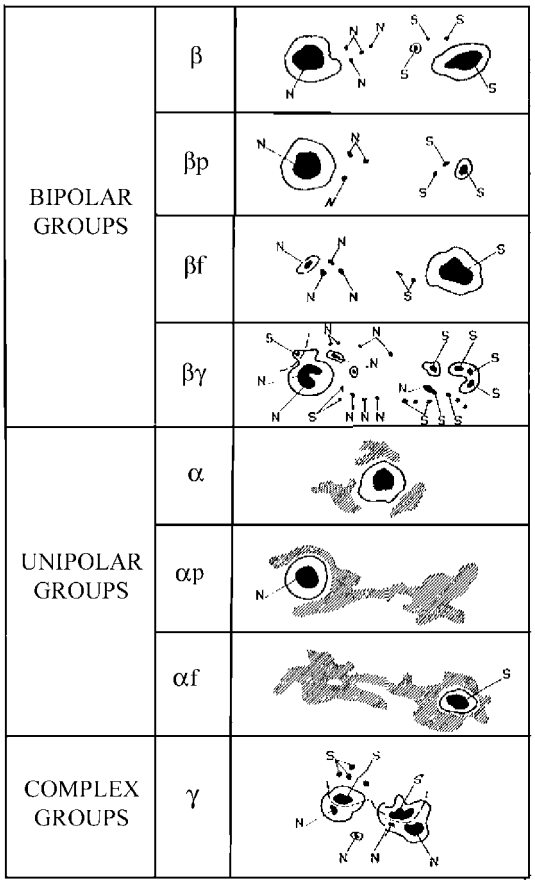

Figure 1. Solar active region classification from Mount Wilson Observatory, based on distribution of magnetic-field polarities of sunspots (from figure 6.4 in Bray and Loughhead 1964). p = preceding spot dominant; f = follower spot dominant. The p-spot 'leads' the spot group as solar rotation moves it from east to west across the solar disk. An additional category, the δ-configuration, was introduced in the 1960s.

Sunspot Classification

Sunspots, dark 'blemishes' on the brilliant solar surface, were discovered telescopically by Galileo and his contemporaries in 1611. Records of exceptionally large, naked-eye sunspots are found in Chinese and Greek records as early as 325 BC. The fortuitous occurrence of smoke or fog darkened the Sun enough to safely reveal the dark spots to the rare observer who would record his surprising view. These spots were mistaken to be birds or some mythical object passing in front of the Sun. It required regular telescopic observations and careful reduction of the observations to deduce the fundamental importance of sunspots.

Sunspots are the manifestation of strong magnetic fields that erupt from below the solar surface. Because this erupting flux is always a system of magnetic-field loops, the intersections of the two 'legs' of the loop-system with the solar surface create a bipolar group of sunspots. Thus

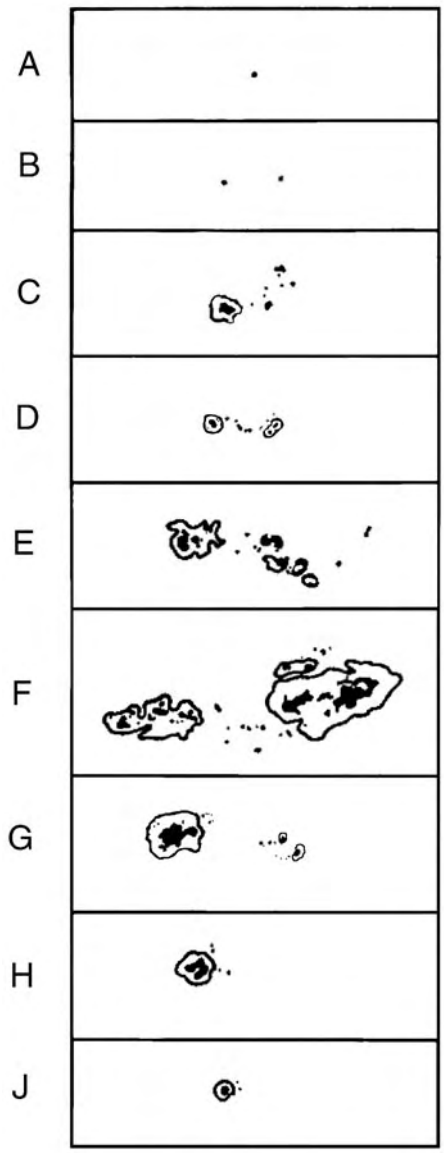

Figure 2. Drawings of typical sunspot groups in each category in the Zurich Sunspot Classification.

the most meaningful descriptive record of sunspots is their appearance in groups.

The sunspot group provides clues about the potential for eruptive activity in an ACTIVE REGION. A description of sunspot groups in a formalized system of classification provides the basis for SOLAR FLARE prediction. It is also a taxonomy of the sunspot phenomenon that becomes one of the essential data in the solar climatic record.

Sunspots are like snowflakes; each one is unique but has size and structure similar to other sunspots. The similarities are the basis for classifying the groups. Early classifications described the evolutionary sequence of a typical, large sunspot group. There was no information

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

about magnetic fields involved with these groups. Regular measurements of magnetic polarities of sunspots led the Mt Wilson Observatory to devise a simple classification scheme based on polarity distributions (figure 1).

The Zurich system (figure 2), in use for most of the 20th century, is still widely used. It describes nine different types of groups. A modification of this system by McIntosh (figure 3) was introduced in 1966 and gradually attained worldwide acceptance by the 1980s. Definitions for this more precise and detailed classification are given below, taken directly from McIntosh (1990).

The Zurich classification was modified and expanded in order to improve the objectivity of the definitions, and to add indicators of size, stability and complexity that appeared to correlate with solar flares. The Zurich system attempts to describe a typical evolutionary sequence for the largest sunspot groups. The Zurich classes are retained in modified form as the first of three components in the new classification. This eases the difficulty in persuading observers to change classification systems. The addition of new parameters takes the form of two simple sequences, expanding the classification to three components. The resulting 60 distinct types of groups produce a more accurate description of sunspot groups than the nine Zurich classes, without demanding much more of the solar observer.

Table 1. Logical sequence for determining McIntosh sunspot types.

Unipolar or bipolar?
Penumbra or no penumbra?
Penumbra on one end or both ends?
Length of group?
Rudimentary or mature penumbra?
Symmetric or asymmetric largest spot?
N–S diameter of largest spot?
Spots between leader and follower?
Mature penumbra in interior?

The general form of the McIntosh classification is Zpc, where Z is the Modified Zurich Class, p is the type of Principal Spot, primarily describing the SUNSPOT PENUMBRA, and c is the degree of Compactness in the interior of the group. Figure 3 illustrates the sequence within each of the three components of the classification. Table 1 lists the logical sequence for determining the McIntosh classification.

The definitions are formulated to require only white-light observations in the interest of consistency among all synoptic observatories. The definitions must begin with the distinction between unipolar and bipolar groups, implying a difference in magnetic topology, but not requiring magnetic-field measurements to make the distinction. Rarely will the measured magnetic class conflict with the following definitions:

Unipolar group. A single spot, or a compact cluster of spots with the greatest separation between spots $\leq 3^\circ$ heliographic (as in a great circle on the solar surface). In the case of a group with penumbra (class H), the greatest separation is measured between the center of the attendant SUNSPOT UMBRA and the nearest border of penumbra surrounding the main spot.

Bipolar group. Two or more spots forming an elongated cluster of length $>3^\circ$. Usually there will be a space near the middle of the cluster dividing it into two distinct parts. Groups with a large principal spot must be $>5^\circ$ in length (i.e., 2.5° plus 3°) to be classified as bipolar.

Modified Zurich class, Z

The modified Zurich classes are defined on the basis of whether penumbra is present, how penumbra is distributed, and by the length of the group. A judgment of complexity is not required, in contrast to the original Zurich definitions. Length is defined in absolute heliographic degrees, *not* as a projection of that length in heliographic longitude (see inset diagram in figure 3). This differs from some of the definitions already in print. The definitions of the classes were adopted from the Zurich classification, with the addition of strict limits to group length. Zurich classes G and J were omitted because they can be described by combinations of these modified Zurich classes with the other two McIntosh components. The illustrations in the left-hand column of figure 3 show typical examples of each class.

A Unipolar group with no penumbra, representing either the formative or final stage of evolution in a spot group.

B Bipolar group without penumbra on any spots.

C Bipolar group with penumbra on one end of the group, in most cases surrounding the largest of the leader umbrae.

D Bipolar group with penumbra on spots at both ends of the group, and with length $\leq 10^\circ$.

E Bipolar group with penumbra on spots at both ends of the group, and with length defined as: $10^\circ <$ length $\leq 15^\circ$.

F Bipolar group with penumbra on spots at both ends of the group, and length $>15^\circ$.

H Unipolar group with penumbra. The principal spot is usually the leader spot remaining from a pre-existing bipolar group

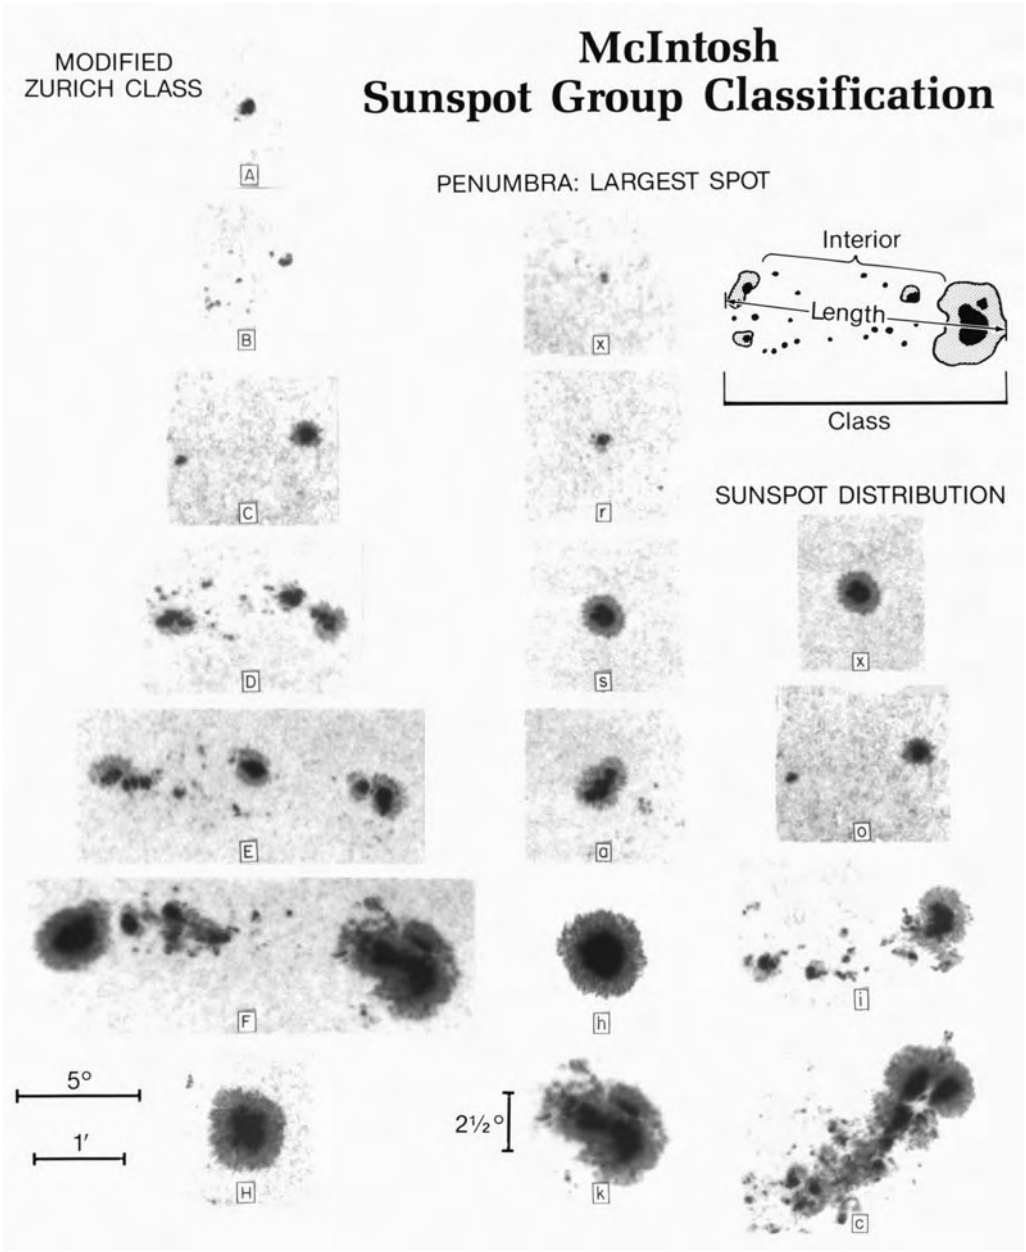

Figure 3. The three-component McIntosh classification illustrated by photographs of typical examples. Images are enlargements from the 15 cm white-light patrol at the Sacramento Peak station of the National Solar Observatory, NOAO.

Penumbra: largest spot *p*

The second parameter of the McIntosh classification is illustrated in the central column of figure 3. The type of largest spot in a sunspot group can be described by the combination of type of penumbra, size of penumbra, and symmetry of penumbra and umbrae within that penumbra. These descriptors specify size, maturity, stability and complexity in terms that are simple and, therefore, conducive to consistent classification.

x No penumbra (group is class A or B)

r Rudimentary penumbra partially surrounds the largest spot
This penumbra is incomplete, granular rather than filamentary, brighter than mature penumbra, and extends as little as 3 arc seconds (2200 km) from the spot umbra. Rudimentary penumbra may be either in a stage of formation or dissolution (McIntosh 1981, §2.3; Bray and Loughhead 1964, plate 3.7).

s Small, symmetric (like Zurich class J)
Largest spot has mature, dark, filamentary penumbra

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of circular or elliptical shape with little irregularity to the border. There is either a single umbra, or a compact cluster of umbrae, mimicking the symmetry of the penumbra. The north–south diameter across the penumbra is $\leq 2.5^\circ$.

a Small, asymmetric
Penumbra of the largest spot is irregular in outline and the multiple umbrae within it are separated. North–south diameter of penumbra $\leq 2.5^\circ$.

h Large, symmetric (like Zurich class H)
Same structure as type 's', but north–south diameter of penumbra $>2.5^\circ$. Area, therefore, must be ≥ 250 millionths of the solar hemisphere.

k Large, asymmetric
Same structure as type 'a', but north–south diameter $>2.5^\circ$ and area ≥ 250 millionths. This type of spot sometimes contains spots of opposite polarity, the Potsdam δ-configuration (Kunzel 1960), and may indicate potential for proton flares (Warwick 1966).

Sunspot distribution, *c*

A simple ranking of the relative spottedness in the interior of a sunspot group gives additional information about the area of the group and, more important, whether there could be strong spots near the line of polarity inversion lying between the principal leader and follower spots. The illustrations in the right-hand column of figure 3 show the extreme examples of open and compact groups, and a typical example of an intermediate degree of spottedness in a group's interior.

x Undefined for unipolar groups (class as A and H)

o Open
Few, if any, spots between leader and follower. Interior spots of very small size. Class E and F groups of *open* category are equivalent to Zurich class G.

i Intermediate
Numerous spots lie between the leading and following portions of the group, but none of them possesses mature penumbra.

c Compact
The area between the leading and following ends of the spot group is populated with many strong spots, with at least one interior spot possessing mature penumbra. The extreme case of compact distribution has the entire spot group enveloped in one continuous penumbral area.

The logic in the definitions of parameters in this classification disallows some combinations of parameters, producing 60 distinct types of sunspot groups (table 2).

Correlations of this classification with x-ray flare occurrence proved that the classification effectively distinguishes between quiescent sunspot regions and those that are nearly certain to produce one or more major solar flares. The isolated, symmetric spots in the central column of figure 3 are typical of those that rarely produce numerous or strong flares. This is consistent with the slow rate of change in symmetric, isolated spots.

Table 2. Allowed types of groups in the McIntosh sunspot classification.

Class	Penumbra: largest spot	Distribution	Number of types
(A)	(x)	(x)	1
(B)	(x)	(o i)	2
(C)	(r s a h k)	(o i)	10
(D E F)	(r)	(o i)	6
(D E F)	(s a h k)	(o i c)	36
(H)	(r s a h k)	(x)	5
Total allowed types			60

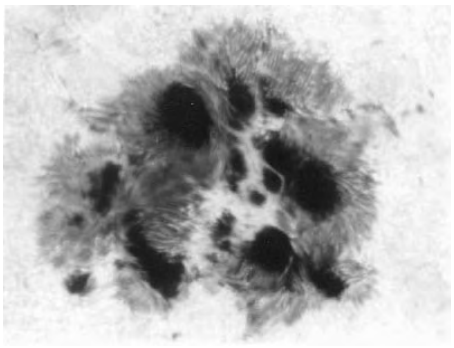

Figure 4. A classic example of a δ-configuration, the inclusion of spots of opposite magnetic polarity in a common area of sunspot penumbra (gray area). This large Dkc-type sunspot group appeared in August 1972. Photograph courtesy of German amateur solar observer G Brueckner.

Figure 4 shows a complex group whose rapid evolution correlated with a series of solar flares, with several of major proportions. This group, seen in August 1972, is a classic example of a δ-configuration, defined as the inclusion of strong spots of opposite polarity within a common area of penumbra. The δ-configuration was added to the Mt Wilson magnetic classification after the work of Kunzel (1960) at the Potsdam Observatory.

See McIntosh (1990) for detailed statistics on flare productivity versus McIntosh sunspot-group types.

Sunspot Cycle

The periodic increase and decrease in the number of sunspots and sunspot groups on the surface of the Sun. The number of spots and groups reaches a maximum, on average, once every 11 years. At the intervening sunspot minima, the solar disk may be devoid of spots for weeks on end. On average, the rise to maximum activity takes 4 to 5 years and the subsequent decline to the next minimum, about 6 to 7 years. The level of activity in successive cycles can vary substantially.

At the beginning of each cycle, spots start to appear at latitudes of about 30° (occasionally as high as 40°) north (+) and south (−) of the solar equator. As the cycle advances, the bands of sunspot activity migrate towards the solar equator. At solar maximum, the average latitude at which spots occur is about ±15°, and by the end of the cycle, around ±8°, by which time the first spots of the next cycle may be beginning to appear at latitudes of 30°–40°. This cyclic variation in the mean latitudes of sunspots was pointed out in 1861 by Friedrich Spörer (1822–95), and is known as Spörer's law. When the latitude of each sunspot is plotted against time over a series of 11-year sunspot cycles, the resulting distribution of spot positions forms a pattern reminiscent of the appearance of butterfly wings and is, therefore, known as the butterfly diagram. A diagram of this kind was first plotted in 1904 by the English astronomer E W Maunder (1851–1928).

In each spot pair, the spot which is ahead, in the sense of the direction in which the Sun rotates, is called the leader, and its companion, the follower. Throughout a complete cycle, from one minimum to the next, all of the spot pairs and groups in the northern hemisphere have the same polarity pattern, and those in the southern hemisphere have the opposite. For example, in one particular cycle, all the leaders in the northern hemisphere will have positive polarity and all the followers negative, whereas all the leaders in the southern hemisphere will have negative polarity and the followers positive. At the end of that cycle, the polarity pattern reverses, so that in the subsequent cycle all northern hemisphere leaders will have negative polarity and all southern hemisphere leaders, positive. The complete magnetic cycle consists of two successive 11-year sunspot cycles and is, therefore, 22 years long.

During the earlier part of each cycle, the leading spot in each pair (or the leading area of net magnetic polarity in each group) has the same magnetic polarity as the net polar polarity in the hemisphere within which it is located. As each spot or group decays, the polarity of the follower preferentially diffuses towards the pole. The cumulative effect of this process eventually produces a reversal of polarity at each of the solar poles. This usually occurs around the time of solar maximum, but considerable variations occur and, while the piecemeal reversal is taking place, the Sun, for a time, may have the same net polarity at both poles.

The sunspot cycle is part of an overall solar cycle whereby all forms of solar activity, including sunspots, plages, prominences, flares and coronal mass ejections, together with the shape, extent and structure of the chromosphere and corona, undergo cyclic variations with a period of about 11 years. The numbers, sizes and energies of prominences, flares and coronal mass ejections mirror the increase and decrease in sunspot numbers and the corona is brighter, more extensive and more symmetrical around solar maximum than at times of minimum activity.

In addition to the 11-year cycle, there is some evidence to suggest that sunspot numbers, and levels of solar activity as a whole, undergo longer-term modulations over periods of 80 years and more. Furthermore, historical records imply that there have been prolonged periods of enhanced and depressed levels of activity in the past. In particular, solar activity appears to have remained at an unusually low level between 1645 and 1715, a period that is known as the Maunder Minimum, having been named after E W Maunder, whose analysis of old solar records showed that hardly any sunspots at all had been seen during that time.

Sunspot Evolution

SUNSPOTS are observed to grow from their first appearance at the solar surface to some maximum size and then to decay until they disappear after some hours, days, or weeks. The characteristics of this growth and decay, the changes during the lifetime of a sunspot group in its distribution of sunspots, surface orientation, magnetic field line inclination, and other characteristic variations give us clues to the subsurface origin of sunspots and to the dynamo process (see DYNAMO THEORY) which produces the magnetic fields that define sunspots.

Sunspots and sunspot groups

Sunspots are dark, generally roughly circular areas in the solar photosphere where there are strong magnetic fields that are approximately vertical to the solar surface in the SUNSPOT UMBRA. These magnetic fields are quite strong—several thousand gauss near the center of the largest sunspots and somewhat weaker in smaller sunspots. The darkest central part (umbra) of a sunspot may have an intensity in the visible part of the spectrum that is only about 5% that of the surrounding solar surface. The outer part of a sunspot (SUNSPOT PENUMBRA) has an intensity much closer to that of the surrounding atmosphere.

Sunspots normally appear in groups of two or more. These are called 'sunspot groups'. Single-spot groups are rare. Sunspot groups are usually aligned along an axis that is oriented approximately (but on average not exactly) in the east–west direction on the Sun. Figure 1 shows an example of a sunspot group with a rather simple configuration. Often the westernmost (leading, in the sense of solar rotation) and easternmost (following, in the sense of solar rotation) sunspots are clearly separated. In general, the leading and following sunspots have opposite magnetic polarities, and this orientation of polarities is predominant in one (north or south) hemisphere during a SOLAR CYCLE. The polarity orientations are opposite in the other hemisphere. Each 11 yr solar cycle has the opposite sunspot-group polarity orientation to the previous solar cycle. One can imagine an axis drawn, connecting the leading and following sunspots (or the centroids of the leading and following collections of sunspots). The angle which this axis makes with the local parallel of latitude is referred to as the 'tilt angle'. The average tilt angle is about +5°, where the plus sign indicates that the leading sunspots are (on average) equatorward of the following sunspots in each hemisphere.

Area development

Sunspot diameters range from around 2000 km to around 30 000 km. A sunspot first appears as a 'pore', which is a very small dark speck within the photospheric granulation pattern. The great majority of SUNSPOT PORES live only for a few tens of minutes, but on rare occasions a pore will grow to become a small sunspot umbra. A sunspot group starts with the appearance of one or more pores, usually in the western (leading in the sense of rotation) portion of the future group. On the second day in the lifetime of the group the small but growing sunspots spread out into an elongated pattern roughly in the east–west direction. This means that individual sunspots move (exhibiting what is called 'proper motion') systematically in such a way as to produce the stretched appearance that is common of normal groups. Leading sunspots move forward (westward), and following sunspots move backward (eastward). This motion often ceases, or slows down, when the group reaches its maximum area. There is also often latitudinal motion at this time, which produces a net rotation of the sunspot group about a vertical axis. This is discussed in more detail below.

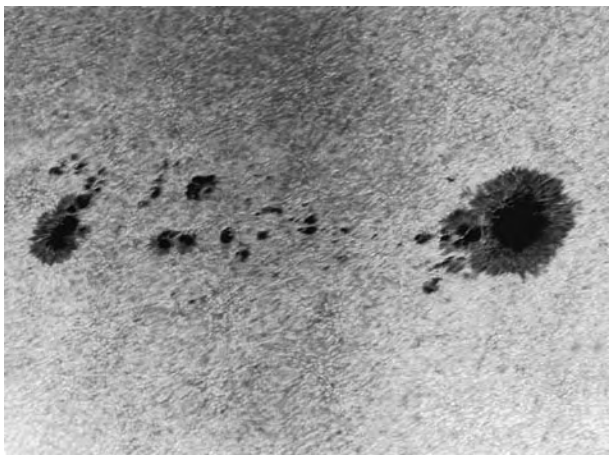

Figure 1. A typical large sunspot group. Note the leading (on the right side) and following (on the left side) sunspots. Also note the very small sunspots (pores) distributed near the group.

As the sunspot group develops in this way, larger sunspots form by the coalescence of smaller sunspots nearby. The smallest sunspots do not have penumbrae. The diameters of penumbrae are generally slightly more than twice those of the associated umbrae. The total area of a sunspot group increases in the first few days of the development of the group, and then quickly the total area begins to decrease until the group has disappeared.

Most sunspots grow rapidly in the first few days after their initial appearance. Sunspots and sunspot groups show a variety of area developments. Some grow and decay slowly. Some groups, especially larger, longer-lived groups, grow rapidly and decay slowly. The decay of a sunspot is not the inverse of the coalescent process that forms sunspots; sunspots decay by the continuing outward flow of bits of the magnetic field, in the form of very small (≈1000 km) parts of the umbra, which are observed to move radially outward through the sunspot penumbra to the photosphere. It is difficult to follow observationally these small magnetic elements as they move from the sunspots. It is presumed that, once they leave the sunspot, they cancel quickly with magnetic fields of opposite polarity in the neighborhood of the sunspot, and there is some observational evidence

for this. Thus sunspots decay by a directed flow of magnetic flux radially outward from the sunspot, which is quite different from the decay of the weaker PLAGE magnetic fields, which always accompany sunspots. Plage magnetic fields decay by the gradual erosion of small elements of magnetic flux from the periphery of the plage. This erosion is caused by nearby, random, large-scale convective motions, which are present at all times over the whole solar surface (except within sunspots and within the plages themselves). This large-scale cellular pattern of convection is called 'supergranulation' (see SOLAR PHOTOSPHERE: SUPERGRANULATION).

Lifetimes

The lifetimes of sunspots range from tens of minutes to months. More than half of sunspots have lifetimes less than 2 days. Ninety per cent of sunspots have lifetimes less than 11 days. Only a few sunspots per 11 yr solar cycle have lifetimes of more than a few months. On average, high-latitude sunspots have relatively short lifetimes. Sunspots with lifetimes of more than several months are extremely rare. The longest-living sunspots are always large, round, single-spot groups, at least in the later stage of their lifetimes. They are generally the last survivors of large, multispot sunspot groups. It is not known why a few sunspots have very long lifetimes, while nearly all sunspots of similar size do not live nearly as long.

A rule of thumb for sunspot group lifetimes is given by the formula

$$T = 0.1A_{max}$$

where T is the lifetime in days and A_{max} is the group area in millionths of the hemisphere.

The sunspots with the shortest lifetimes are very small (no more than a few thousand kilometers in diameter) and have no penumbrae. These smallest sunspots have lifetimes of only a few hours, if they do not grow into full-sized sunspots, as discussed above. The vast majority of sunspots do not develop beyond the pore stage. Pores (that do not develop into sunspots) may live for only a few tens of minutes. Often sunspot groups, especially in the earlier stage of their development, have many pores associated with them at any one time. Note the pores associated with the sunspot group in figure 1.

Magnetic fields

Magnetic fields may be considered to define sunspots. That is to say, all sunspots contain strong magnetic fields. These magnetic fields, in the highly ionized solar gas, impede the convection process which in the normal photosphere is the principal mechanism for the transport of thermal energy from deep within the solar interior. Thus sunspots are darker than the surrounding photosphere (although in an absolute sense they are still quite bright).

Measurements of magnetic field strengths within sunspots are difficult because of the presence of scattered light from the much brighter photosphere surrounding the sunspot. These problems are especially severe for the smallest sunspots. Field strengths of several thousand gauss are measured in the largest sunspots. These represent maximum values, which are generally found at the center of the umbra. Field strengths decrease as one measures closer to the umbra–penumbra boundary.

These sunspot field strengths are observed to increase rapidly in the initial growth stage of a sunspot and then remain relatively constant for a large part of the lifetime of the sunspot. A decrease in the field strength occurs only in the last stages of decay of the sunspot. This is in contrast to the behavior of the sunspot area, discussed above, which generally also increases rapidly following the first appearance of the sunspot but which then begins to decrease shortly after the sunspot reaches its maximum size. The magnetic flux, of course, which may be considered to be the product of the area and the magnetic field strength, shows the behavior of the area during the lifetime of the sunspot. That is, the flux increases rapidly and then it quickly begins its slow decline until the sunspot disappears.

Orientations

Surface orientations

As discussed above, one of the observable characteristics of a sunspot group is its tilt angle. There is considerable dispersion in the tilt angles around the average tilt angle (+5°) mentioned above. In general about 36% of sunspot groups have tilt angles within 10° on either side of the average angle. Only about 13% of sunspot groups have tilt angles more than 45° from the average angle in either direction. Extreme tilt angles result in magnetic polarity orientations that are reversed from the normal, i.e. where the leading magnetic polarity sunspots are located east of (or following in the sense of solar rotation) the following magnetic polarity sunspots. Nearly 10% of groups show such reversed-polarity orientations. Many of these are small sunspot groups.

It is generally believed that the magnetic fields of sunspot groups rise to the surface as large loops of magnetic field lines from the base of the solar convection zone, which means from about one-third of a radius below the surface. As these loops rise through the solar convection zone, propelled by the buoyant force on the ionized gas that is confined to the magnetic field lines, they are acted upon by various physical forces. One of these forces is the Coriolis force, which will act to twist the plane of the loop (which is assumed to start its rise aligned in the east–west direction). Another force that acts on the rising magnetic flux loop is magnetic tension, which acts to restrain the rise of the flux loop and other motions of the loop. Mathematical models of these forces indicate that the twist of the axis that one would expect from such theoretical considerations is about what is observed as the average tilt angle in each hemisphere. Moreover, the variation of tilt angle with latitude that is observed (known as Joy's law) can also be reproduced in the theoretical models. Other observed characteristics of sunspot groups

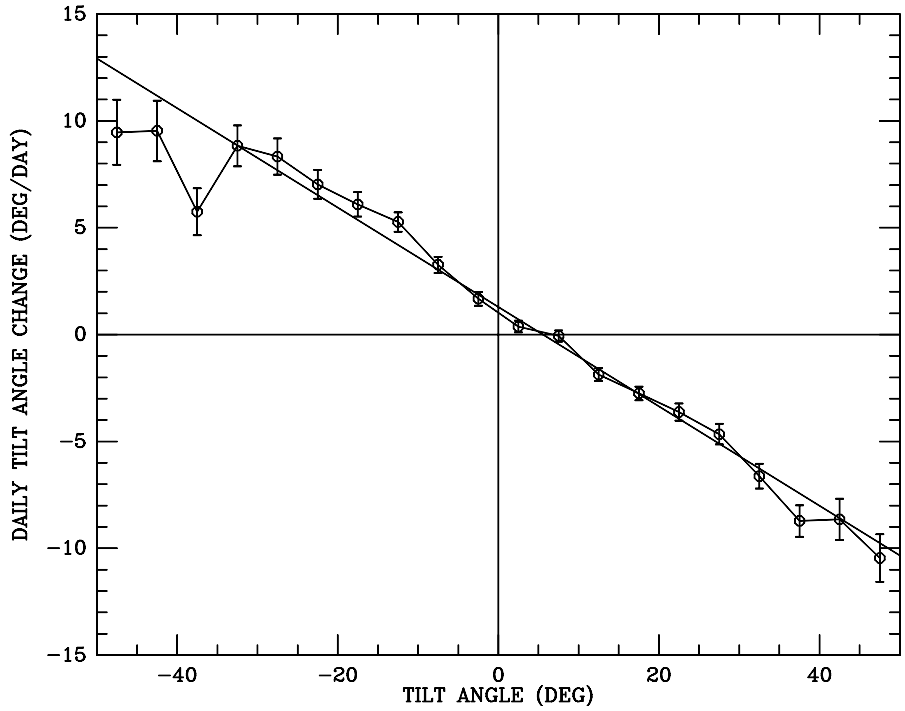

Figure 2. Average value of the daily rotation of the magnetic axes of sunspot groups (tilt angles) for various values of the starting tilt angle. Note that the intercept on the Y-axis of the plot is at 5°, not at 0°. This indicates that sunspot group tilt angles tend to rotate toward the average tilt angle, not toward the east–west direction (0°).

can also be seen in the calculations of these mathematical models.

In addition to these physical forces, the rising magnetic flux loops will be subjected to added random twisting from large-scale convective motions that exist deep within the solar convection zone. It is believed that these random interactions are responsible for the dispersion in tilt angles that is observed in sunspot groups. Smaller sunspot groups show a larger dispersion about the average tilt angle than do larger sunspot groups. This is what one would expect to find if large-scale motions of the gas are responsible for the distribution in the tilt angles: the magnetic flux loops of the larger and stronger sunspot groups can withstand such buffeting from the convective motions better than can the smaller and weaker flux loops, and thus they show a smaller dispersion in their tilt angles.

Magnetic field-line inclinations

Sunspot magnetic field orientations to the vertical (in the east–west direction) can be estimated by examining the areas or magnetic field strengths of sunspots east and west of the central MERIDIAN of the Sun (the north–south meridian that is coincident with the rotation axis on the projected image of the Sun). It is assumed that the east–west differences in area or magnetic field strength are due to east–west orientations of the field lines in the solar atmosphere. In principle it should be possible to measure inclinations of sunspot magnetic fields by the measurement of the vector magnetic field in the sunspots, but in practice this is difficult to do with high precision for the small inclinations that are known to exist in sunspots. The transverse ZEEMAN EFFECT (measuring field strength in field lines perpendicular to the line of sight) is not nearly as sensitive a measure of field strength as is the longitudinal Zeeman effect (along the field lines) measurement.

On average, using this east–west difference technique, the magnetic field lines of sunspots are found to be inclined a few degrees to the east, that is, to trail the rotation—which is from east to west. The inclinations of the leading and following sunspots in the groups are on average away from each other by a degree or so. This means that the following sunspot magnetic fields are inclined to the east by a slightly greater angle than are the leading sunspot magnetic fields. Sunspots whose areas are growing (therefore, presumably younger sunspots) show greater eastward inclination of their magnetic field lines by several degrees than do sunspots whose areas are decreasing. Thus we conclude that during the lifetime of the group there is a shift in the inclination angle toward the west.

Tilt angle changes

Sunspot group tilt angles are sometimes observed to change with time. This means that the axes of the groups rotate (in the plane of the solar surface). This rotation is generally very slow. Very few sunspot groups show

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

rapid rotation about their axes, and, when they do, it is usually early in the development of the group. Fully 46% of sunspot groups show daily rates of rotation of their axes of less than 10° in either direction. Only about 14% of sunspot groups on any one day have rotation rates greater than 45° day^{-1} in either direction.

However, although generally sunspot group axis rotations are slow, they tend to exhibit systematic motions. On average, sunspot group axes rotate in the direction toward the average tilt angle in each hemisphere, as may be seen in figure 2. Another way of stating this is that on average the only tilt angles for which there is no average tilt angle rotation is the average tilt angle. This is represented in the figure as the intercept on the X-axis. This intercept is located at the average tilt angle of about 5° rather than at the origin. This is a result that is clearly above the noise level.

This rotation of the axes of sunspot groups is not understood by astronomers in the context of our current view of the origin of the magnetic fields at the solar surface. It is possible that the various physical forces that act on the sunspot magnetic flux loop as it rises through the solar interior can twist the flux loop, as mentioned above, but once the magnetic fields reach the surface it is difficult to explain any further rotation of the magnetic axis of a group. Because of the motions of the subsurface, large-scale turbulent convection, which as we saw above may be responsible for the dispersion of the sunspot group tilt angles, it is difficult to understand how there can be within the convection zone any fixed location where the ends of the magnetic loop could be anchored. It is equally difficult to understand how the surface orientation could possibly be affected by the orientation of the magnetic flux loop at the base of the convection zone, which is one-third of a radius beneath the solar surface.

One possible explanation for this curious behavior of the magnetic axes of sunspot groups is that there is, in fact, no real rotation motion at all of the tilt angle in growing sunspot groups. Rather, the plane of the magnetic flux loop that makes up the sunspot group has become twisted within the convection zone, and as it rises it gives the appearance of a rotary motion at the plane of the surface.

Sunspot Magnetic Fields

The magnetic field is the central quantity determining the property of a SUNSPOT. It permeates every part of sunspots and by greatly reducing the convective transport of heat from below is also responsible for sunspot darkness. Conversely, sunspots were the first astronomical objects recognized (by G E Hale in 1908) to harbor a magnetic field.

The field strength B is most readily measured in the photospheric layers. There it reaches peak values of 2000–3500 G (i.e. 0.2–0.35 T) in parts of the sunspot umbra (the spread in values is intrinsic—larger sunspots have higher maximum field strengths). The field strength drops steadily towards the edge of the sunspot, where it is 700–1000 G (0.07–0.1 T). The strongest field within a sunspot is usually associated with the darkest part of the umbra (umbral core) and is generally close to vertical, while at the visible sunspot boundary it is inclined by 70–80° to the vertical. The magnetic structure of a mature sunspot is illustrated in Color Plate 53.

The magnetic field of a sunspot nevertheless continues well beyond its white-light boundary as an almost horizontal magnetic canopy with a base in the mid to upper photosphere. The field strength above the height of the canopy base continues to decrease slowly but steadily for increasing distance from the white-light sunspot. The field strength also decreases with height, with the decrease being more rapid in the photosphere than in higher atmospheric layers.

These observed properties of sunspot magnetic fields support the theoretical concept that visible-light sunspots are the intersection of the solar surface with a large magnetic flux tube emerging from the solar interior into the atmosphere.

At small scales the umbral magnetic field appears to be relatively homogeneous, while the penumbral field is filamented into two radially directed components. These differ by their inclination to the vertical, and possibly also their field strength.

In this article the observed magnetic structure of (mature) sunspots is discussed. The theoretical description of the field structure is outlined in the article SUNSPOT MODELS and the magnetic field of pores (i.e. dark magnetic structures without a penumbra) in the article SUNSPOT PORES.

Overviews of the observed magnetic structure of sunspots have been given by Martínez Pillet (1997) and Skumanich *et al* (1994), and may be found in the volume edited by Thomas and Weiss (1992).

Large-scale magnetic structure of sunspots

The field strength

The magnetic field of sunspots in photospheric layers has been measured via the Zeeman splitting of absorption lines in the visible and the infrared (see the article on SOLAR MAGNETIC FIELD: INFERENCE BY POLARIMETRY and on SOLAR MAGNETIC FIELD: ZEEMAN AND HANLE EFFECTS). The magnetic field strength is largest near the geometrical center of regular, i.e. reasonably circular, sunspots and drops monotonically and smoothly outwards, reaching its smallest values at the outer penumbral edge. This is in stark contrast to the brightness, which jumps at the boundary between the umbra and penumbra. Hence, the umbral boundary is not evident in the field strength. This simple picture of a relatively smooth magnetic distribution is valid for a spatial resolution of 2–3″ or lower. At higher resolution the fine-scale structure of the field becomes increasingly prominent (see below).

There is now a consensus on the general form of the normalized field-strength distribution, $B(r/r_p)/B_0$, although some uncertainty concerning its exact shape remains. Here r is the radial coordinate, r_p is the radius of the outer penumbral boundary and B_0 is the (maximum) field strength at the center of the sunspot (i.e. at $r = 0$). The radial dependence for typical sunspots of the three components of the magnetic field is plotted in figure 1B. Magnetic dipole fits to such data are reasonable, but not perfect in many cases.

The maximum field strength (i.e. B_0) increases almost linearly with sunspot diameter from $B_0 \approx 2000$ G for the smallest spots to over 3500 G for the largest spots. At the sunspot boundary $B(r_p) \approx 700$–1000 G, which implies $B(r_p)/B_0 \approx 0.2$–0.4. The fact that $B(r_p)$ is so large suggests that sunspots are bounded by a current sheet.

Magnetic field orientation

The strongest part of the sunspot magnetic field is in general also the most vertical. Inclination to the vertical (i.e. zenith angle, ζ) increases steadily as the field strength decreases. For symmetric sunspots ζ also increases steadily with r, i.e. the field is increasingly inclined to the vertical the further out in the sunspot that it is measured. Recent evidence suggests that the inclination is 10–20° to the horizontal (i.e. $\zeta \approx 70$–$80°$) at the sunspot boundary. Typical $\zeta(r/r_p)$ values are plotted in figure 1C.

Early vector-magnetograph observations often suggested that the magnetic field of regular sunspots is significantly twisted. These strong twists or spirals were an artefact of neglecting magneto-optical effects, however. Once such effects are included in the analysis the magnetic fields of regular sunspots become almost radial. A small residual twist of up to 10–20° still appears to persist, however. A residual twist is not entirely surprising considering the fact that the superpenumbral fibrils seen in Hα are increasingly twisted with increasing distance from the sunspot.

Magnetic canopy

Above the solar surface the magnetic field continues beyond the white-light boundary of sunspots. It forms an almost horizontal canopy with a base in the middle or upper photosphere, i.e. the field is limited to layers above the canopy base and overlies mainly field-free gas. The magnetic canopy is a natural result of the expansion with height of the magnetic flux tube underlying the sunspot. Recall that the visible sunspot is just a cross section through

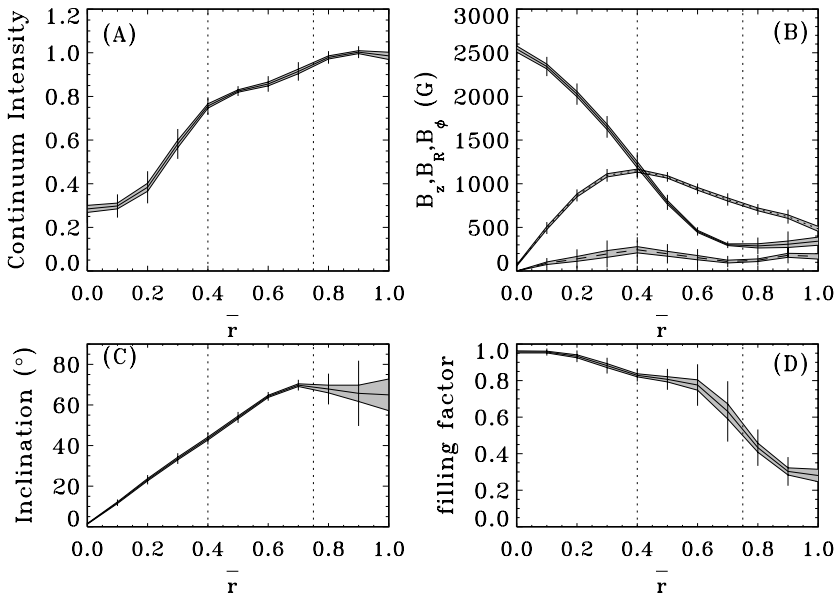

Figure 1. Typical intensity and magnetic parameters of sunspots versus normalized radial distance, $\bar{r}$, from sunspot center. Vertical dotted lines indicate the umbra–penumbra (left) and the penumbra–canopy (right) boundaries. Plotted are the continuum intensity in panel A, vertical (B_z, solid curve), radial (B_r, dotted curve) and azimuthal (B_ϕ, dashed curve) components of the magnetic field in panel B, magnetic inclination in panel C and magnetic filling factor in panel D. $\bar{r}$ is normalized to the radius at which the canopy could not be seen anymore. (From Keppens and Martínez Pillet (1996) with permission.)

this flux tube. In this picture the canopy base corresponds to the current sheet surrounding the sunspot.

$B(r/r_p > 1)$ is found to decrease continuously without any visible break at the white-light boundary of the sunspot. The base height of the canopy increases relatively rapidly close to the sunspot. However, this rise soon slows, so that the canopy can be followed out to almost twice the sunspot radius using purely photospheric lines.

Sunspot canopies were first discovered by W Livingston in magnetograms taken in spectral lines formed in the upper photosphere and lower chromosphere, where they appear as large diffuse patches of field filling the limbward and discward superpenumbrae of sunspots observed near the solar limb. Newer techniques also allow canopies to be detected when the sunspot is close to disc center. They all give roughly consistent results.

Return flux and depth of the penumbra

Inside the penumbra the general inclination of the magnetic field suggests that a considerable amount of magnetic flux is emerging through the penumbra. An analysis based on the premise that the sunspot magnetic field is potential inside the bounding current sheet allows more quantitative estimates to be made and suggests that approximately 1–1.5 times as much magnetic flux emerges in the penumbra as in the umbra. The penumbra is thus deep, in contrast to a shallow penumbra in which the current sheet bounding the flux tube lies along the solar surface in the penumbra and no magnetic flux emerges there.

A relatively small fraction of the total flux emerging in a sunspot returns to the surface inside or just outside the sunspot boundary. This so-called 'return flux' has been observed at some locations along the boundary of the sunspot. These locations are co-spatial with downflows which are interpreted as a part of the Evershed flow draining down into the solar interior again.

Vertical gradient of the magnetic field

In addition to the large number of observations in the lower and central photospheric layers the sunspot magnetic field has been recorded at greater heights as well.

Basically, the observations suggest that the maximum field strength at the center of regular sunspots decreases with height, but still has values of 1000–1800 G in the upper chromospheric to lower coronal layers. The magnetic field is in general more homogeneous in the upper atmosphere. It can be followed over a larger distance in the upper atmosphere and decreases more slowly with distance from the sunspot axis.

Nevertheless, the field in the coronal layer is often more confined than expected from a dipole fit to photospheric observations and provides evidence for non-potential fields. On the other hand in parts of an active region coronal fields are well reproduced by potential field extrapolations from the photosphere.

Knowledge of the magnetic field at different heights allows vertical gradients of the field strength to be determined (and to be compared with the predictions of models). The values of the obtained vertical gradient

depend on both the horizontal position in the sunspot and the height range over which they are measured (i.e. the formation height difference between the two diagnostics used).

First consider measurements comparing lines formed in the photosphere, i.e. those determining $|\partial B/\partial z|$ over a small height range. These give values around 2–3 G km^{-1} in the umbra and inner parts of the penumbra, dropping to around 1 G km^{-1} in the outer penumbra.

When lines formed at sufficiently different heights are compared (i.e. usually a photospheric line with either a chromospheric or transition region line, or a coronal diagnostic) then considerably smaller vertical gradients are obtained: 0.3–0.6 G km^{-1} in the umbra, which drops to 0.05–0.2 G km^{-1} near the outer penumbral edge. This dependence on radial position can also be parametrized as $|\partial B/\partial z| \sim |B|$.

The observations therefore suggest that the field strength drops rapidly with height in the photosphere and much more slowly at greater heights. The qualitative height dependence agrees with the expectations of a flux-tube model. Almost all the observations also indicate a decrease of $|\partial B/\partial z|$ from the center of the sunspot toward its periphery (or from stronger to weaker field).

Fine-scale structure of the magnetic field

The fine-scale structure visible in white-light images of sunspots is predominantly due to umbral dots and light bridges (see SUNSPOT UMBRA: STRUCTURE AND EVOLUTION) and to penumbral filaments. These and related features are also prominent in filtergrams, although at the greater heights sampled by some filtergrams somewhat larger scales may dominate. As far as the magnetic field is concerned the main known inhomogeneities are concentrated in the penumbra (see SUNSPOT PENUMBRA: STRUCTURE AND ACTIVITY).

Umbral dots

Umbral dots are bright dot-like features with horizontal dimensions often lying at the limit of the spatial resolution. Various investigators have searched for the signature of umbral dots in the magnetic field. Whereas older observations showed a huge scatter in deduced field strength values, there has been convergence toward a rough consensus in recent years. The investigations carried out in the 1980s and 1990s suggest that the field strength in an umbral dot is at the most 20% lower than in the surrounding umbral background.

Such a reduction in field strength in umbral dots may well be due to the fact that B decreases with height and the observed radiation is emitted from higher layers in hot and bright regions, so that at a given geometrical height the field may be equally strong in the dot and outside it.

Fluted magnetic field in the penumbra

The azimuthal inhomogeneity on small scales of the penumbral magnetic field, in particular of its zenith angle, is now well established.

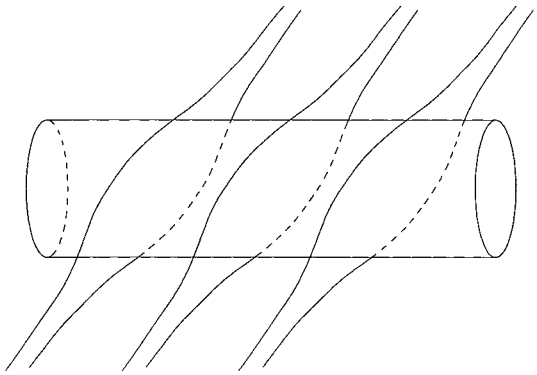

Figure 2. Sketch of the local fine-scale structure of the magnetic field in sunspot penumbras. The field is composed of two components, a flux-tube component, represented by the horizontal cylinder, and a more inclined magnetic field, indicated by the field lines crossing the flux tube at an angle (from Solanki and Montavon 1993).

Less clear than the mere presence of fluctuations in the zenith angle ζ is the correlation of the zenith angle with brightness at a fixed distance from the center of the sunspot. All three possibilities, namely positive, negative and no significant correlation have been proposed in the literature. There does appear to be a significant correlation of ζ with the velocity, however, with the flow being concentrated in the horizontal magnetic filaments. The fine-scale structure of the penumbral field remains remarkably constant on a time-scale of minutes to hours.

Another point that is not completely decided is whether, in addition to the inclination, also the field strength in the penumbra is inhomogeneous in the azimuthal direction. Some investigators see no fluctuations in B, while others find 100–400 G higher B values in dark penumbral fibrils than in their bright counterparts. Yet others see evidence for weaker fields in cooler parts of the penumbra. A final group of researchers observe that the more vertical filaments have a 200 G higher field strength.

From a combination of high-resolution imaging and broad-band circular polarization (BBCP) measurements it follows that there must be a horizontal boundary between the two differently inclined magnetic components in the penumbra. Hence they cannot simply be vertical sheets of magnetic flux. The penumbral fine-scale field is better described by (more or less) horizontal flux tubes embedded in an inclined field, as illustrated in figure 2. The width of the cross-section of these flux tubes is as yet uncertain.

Magnetic filling factor

In order to explain phenomena such as umbral dots the intrusion of field-free material into umbras at small scales has been proposed. In addition, the presence of field-free material in penumbras could resolve the mass-flux problem of the Evershed effect in a rather straightforward

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

manner. In general, only upper limits on the area coverage by field-free material inside sunspots can be given. The exceptions are light bridges, i.e. bright material separating two umbras within a single sunspot, which exhibit direct evidence for the presence of narrow lanes of field-free material in sunspots.

The upper limit lies at 5% in the central penumbra and at 3–4% in the central part of the umbra. Near the umbral boundary the upper limit lies around 15% and is also large close to the outer penumbral boundary. Figure 1D shows an example of less stringent upper limits on the amount of field-free material (or rather of a lower limit on the magnetic filling factor, i.e. the area fraction covered by the field). One caveat to keep in mind when considering these very tight limits is that they refer mainly to mid-photospheric layers. Since the magnetic energy begins to dominate over that of the gas at these heights, but does not in the lower photosphere, it is far more likely that if field-free patches exist that they are located in the lower photosphere. In the lower layers of sunpots the upper limit is less tight, with the most stringent value being 5% in the central penumbra.

Sunspot Models

Models of SUNSPOTS aim either to reproduce observed properties of sunspots, or to understand the physical processes occurring in them. Sunspot models are of very diverse types, ranging from empirically derived models of their thermal stratification to MHD models of their magnetic configuration and evolution. The final aim of all modelling is to obtain a consistent and detailed description and understanding of the structure and dynamics of the magnetic and thermodynamic properties of a sunspot. Such comprehensive models are not feasible as yet. Hence most models deal with some aspect of sunspots in detail, while neglecting or simplifying the other aspects. Most numerous among the physical models are those describing the magnetic structure of a sunspot (see article SUNSPOT MAGNETIC FIELDS) on the basis of an axially symmetric vertical flux tube in (approximate) magnetohydrostatic equilibrium. Another group of physical models deals with the other main characteristic of sunspots, namely their darkness relative to the quiet Sun. They model the heat flow by radiation and convection in and sometimes also around the sunspot. The models with the most detailed description of energy transport, e.g. an explicit simulation of magnetoconvection, generally treat only a part of the sunspot (e.g. a part of the SUNSPOT UMBRA). In the most comprehensive models, in which the magnetic field structure of the whole sunspot is determined, the convection is usually dealt with using the mixing length formalism.

In this article a description of physical models of the magnetic and thermal structure of sunspots is given. Physical models of other features of sunspots, e.g. the Evershed effect or sunspot oscillations, are to be found in other articles (see SUNSPOTS: EVERSHED EFFECT, SUNSPOT OSCILLATIONS AND SEISMOLOGY). The same is true for empirical models, i.e. models of the sunspot magnetic or thermal structure that are derived from observations.

Since the thermal and magnetic structure of sunspots is known in considerable detail from observations, rather tight constraints can be set on physical models. One obvious difference between actual and modeled sunspots is that whereas the former are generally irregular, the latter almost always possess axial symmetry. However, relatively regular sunspots do exist, which can be used to test whether the models reproduce the observed radial dependence of the field strength, field direction, brightness, Wilson depression, etc. Although models in many cases provide reasonable descriptions of sunspots and can reproduce many observations, they provide far fewer *ab initio* explanations. There is as yet no satisfactory explanation for such basic questions as to why sunspots have penumbras, or why umbras carry 20% and penumbras 75% of the heat flux of the quiet Sun (see SUNSPOT PENUMBRA).

Theoretical models of solar magnetic features can be divided into three classes. Firstly, there are numerical experiments, usually idealized simulations of some physical process, such as magnetoconvection, thought to act in the magnetic feature. The second class is composed of static descriptions of symmetric flux tubes that aim to reproduce the global observed properties of sunspots at the cost of some physical realism. Finally, full-fledged simulations make up the third class. These include time dependence, compressibility, partial ionization, radiative transfer, two- or, ideally, three-dimensionality, a fine spatial and temporal grid and a sufficiently large computational domain.

Unfortunately, the large size of sunspots and the small-scale structure dominating many of the dynamic processes within them conspire to make the third class of models beyond current reach. The large spectrum of time scales relevant to the problem make it even more intractible. Such simulations do exist for small-scale magnetic features (magnetic elements), however, and it is basically insufficient computing power which keeps sunspots from being similarly described.

Further details, and in particular further references, about models of the thermal and magnetic structure of sunspots are to be found in the following reviews: Nordlund and Stein (1990), Thomas and Weiss (1992), Jahn (1997) and Weiss (1997).

Models of the magnetic structure of sunspots

Sunspots are thought to be the cross sections at the solar surface of large, nearly vertically oriented magnetic flux tubes (see SOLAR INTERIOR: EMERGING MAGNETIC FLUX TUBES). Hence the large-scale magnetic structure of sunspots is generally represented by axially symmetric flux tubes. Most models of the magnetic structure are calculated in the magnetohydrostatic approximation, i.e. they neglect evolutionary aspects, convective motions, the Evershed effect and the influence of waves and oscillations. For the overall structure of the magnetic field this is a good approximation since sunspots evolve on time scales far longer than the time taken by disturbances travelling at the Alfvén speed or sound speed to cross them (the Alfvén transit time is only an hour). Dynamic phenomena are important, however, for shaping the small-scale magnetic (and thermal) structure which is particularly prominent in the penumbra (penumbral filaments or fibrils), but is also seen in umbras (umbral dots). Most models of the whole sunspot neglect the fine-scale structure in the interests of tractability.

The sunspot magnetic field is confined horizontally by a combination of the excess gas pressure in the field-free surroundings of the sunspot and magnetic curvature forces. In contrast to small magnetic flux tubes the latter cannot be neglected, making the modeling of the sunspot magnetic field far more challenging. The magnetohydrostatic equilibrium is described by the force balance equation and one of Maxwell's equations:

$$\frac{1}{4\pi}\,\mathrm{curl}\,\boldsymbol{B}\times\boldsymbol{B}=\nabla p-\rho\boldsymbol{g}$$

$$\mathrm{div}\,\boldsymbol{B}=0$$

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

where $\boldsymbol{B}$ is the magnetic vector, p is the gas pressure, ρ denotes the density and $\boldsymbol{g}$ is gravitational acceleration. Hydrostatic equilibrium along field lines is already implicit in the force balance equation. Usually significant additional assumptions are made, since the computation of the magnetic configuration without further assumptions requires the simultaneous and consistent solution for the magnetic and thermodynamic structures, which in turn requires the solution of an energy equation in addition to the above equations. Most such 'comprehensive' solutions that have been attempted are not general since the magnetic structure is often partially prescribed and the thermodynamics are greatly simplified, although recently significant progress has been made on both accounts. Unless the energy equation is solved together with the force-balance equation either the magnetic field or the temperature must be specified and an equation of state must be postulated. Instead of the temperature distribution the pressure can also be specified.

Types of magnetic solutions that have been investigated include similarity solutions, return-flux models, force-free models, current-sheet models and models with arbitrary horizontal pressure distributions. Before considering these particular solutions, however, we need to distinguish between some basic configurations.

Monolith versus cluster models

One basic assumption underlying all attempts to quantitatively model the global magnetic structure of sunspots is the assumption that the sunspot is monolithic below the solar surface, i.e. that it can be represented by a single flux tube. Since these layers are not directly accessible to observations, this assumption cannot be rigorously tested, although the techniques of local helioseismology can in principle set some constraints on the subsurface field (see SOLAR INTERIOR: LOCAL HELIOSEISMOLOGY).

It has been proposed that just below the surface the magnetic field of a sunspot breaks up into many small flux tubes due to the fluting or interchange instability. In this instability, the magnetic energy of the system is lowered by the break up of a large flux tube (with strong magnetic curvature terms) into many small ones (with small curvature terms). Later it was found, however, that magnetic buoyancy can save sunspots ($\phi > 10^{20}$ Mx) from going unstable to fluting, so that this argument does not favor the production of subsurface 'spaghetti'. This model is often referred to as the spaghetti model or jellyfish model. Nevertheless, a cluster model of sunspots (see figure 1) has the advantage that it can readily explain the high thermal flux seen in the umbra, as well as umbral dots in a natural manner (as field-free intrusions into the sunspot). The complex magnetic structure in the penumbra, in which fibrils or filaments of field pointing in different directions are interlaced, suggests that the magnetic field is indeed concentrated into many small flux tubes.

One argument against the cluster model is that the potential field in the observable layers produced by a collection of buried magnetic monopoles held together at great depth has a maximum strength that increases too strongly with the number of monopoles. It increases much more rapidly with the size of the spot than shown by the observations. To what extent a flux-tube cluster is described by a group of magnetic monopoles is unclear, however. Another reason why the cluster is not expected to be too loosely constructed is that the observed radial dependence of the field is not too different from a buried dipole (figure 2), which is prototypical of a monolithic flux tube

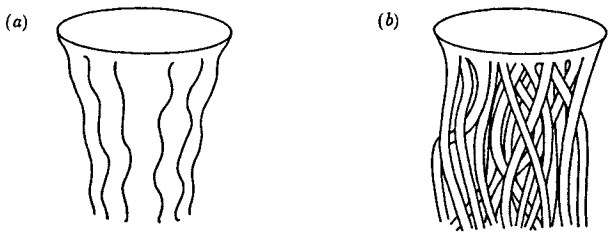

Figure 1. Sketch of the monolithic (left) and cluster (right) models of sunspots. (From Thomas and Weiss 1992 by permission.)

Self-similar models

In such models the radial dependence of $\boldsymbol{B}$ at a given constant geometrical height is prescribed and is imposed to be the same at all heights, except for a scaling to take into account the expansion of the field with height. Hence the name similarity models or self-similar models. This prescription allows the vertical and radial magnetic coordinates to be separated

$$B_z = f(r/R(z))B_0(z)$$

$$B_r = -\frac{r}{2}\, f(r/R(z))\frac{\mathrm{d}B_0}{\mathrm{d}z}(z)$$

and only an ordinary differential equation for $B_0(z)$, the field strength along the flux-tube axis, needs be solved. $f(r/R)$ is called the shape function. In most applications a Gaussian shape function has been chosen.

Due to their simplicity such models have attracted considerable attention. Some self-similar models include a description of energy balance, for others the pressure difference between the axis and the field-free surroundings of the sunspot is prescribed at all heights (e.g. by taking it from empirical models in the observable layers).

Self-similar models, although straightforward to construct, may be too restrictive to describe sunspots accurately. For example, classical similarity models have great difficulty reproducing the observed continuum structure of sunspots composed of a central umbra surrounded by a penumbra. These models usually produce a bright ring, usually located near the umbra–penumbra boundary, contrary to observations. This anomaly, which may be an artifact of the particular choice of the shape function, has so far only been removed by

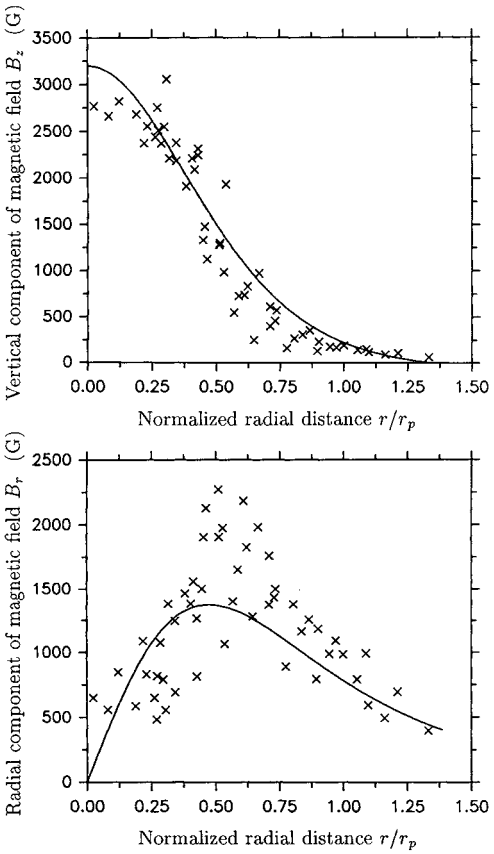

Figure 2. Fit of a buried dipole (solid curves) to the measured $B_z(r/r_p)$ in (*a*) and to $B_r(r/r_p)$ in (*b*). The observations are represented by crosses. Here B_z is the vertical and B_r is the radial component of the magnetic vector, r is the radial coordinate measured from the geometrical center of the sunspot and r_p is the outer radius of the penumbra.

ad hoc changes in the thermodynamic structure. A more basic limitation of self-similar models applies to their upper layers. The magnetic field of sunspots, like that of small flux tubes, expands nearly exponentially with height. If, for example, the field is nearly potential or force-free inside a boundary current sheet (which is the case above the SOLAR PHOTOSPHERE), then the rapidity of this expansion influences the radial distribution of the field. The more strongly the field expands the more strongly the field strength decreases towards the edge of the flux tube. Since the rate of expansion itself increases significantly from the SOLAR INTERIOR to its outer atmosphere the correct description of the magnetic field near the solar surface does not automatically imply that the field is also correctly described below the surface or high in the atmosphere (above the lower coronal boundary, where radio observations can be used to measure it).

More realistic self-similar solutions may be obtained by including the Wilson depression (see SUNSPOTS: WILSON EFFECT) and its observed horizontal variation when determining the shape function $f(r/R)$ from the observed radial dependence of the magnetic field (which is known along a level of constant optical depth). These models reproduce a fair number of observations.

Return-flux models

Self-similar models have been extended to include field lines in the outer part of the sunspot which return to the solar surface just outside the visible sunspot (return-flux model). In this model the emerging return flux is said to constitute the penumbra. Since observations suggest that approximately half of the magnetic flux of a sunspot emerges in the penumbra this also provides an estimate of the amount of return flux that is present according to this model. This model, however, finds little support from observations, since the amount of opposite polarity flux seen in the immediate surroundings of sunspots is small. The observed return flux appears to be related to the horizontal field strands carrying the Evershed flow and is only seen in the lowest observable layers at some locations at the periphery of the sunspot. A dominant fraction of the flux continues in the magnetic canopy which surrounds the sunspot (a layer of almost horizontal field overlying a field-free layer). For realistic parameters the predicted continuum intensity of return-flux models is not much closer to the observations than for the standard self-similar models.

Force-free and potential field models

The magnetic field is called force free when the terms describing the influence of the gas (and the gravity), i.e. the terms on the right-hand side of the force balance equation, can be neglected (force-free fields) (see FORCE-FREE MAGNETIC FIELDS). In that case the force balance reduces to

$$\text{curl}\, \boldsymbol{B} = \alpha \boldsymbol{B}.$$

In general, α is a scalar function of the spatial coordinates and is constant along field lines (as can be seen by taking the divergence of the above equation). Solutions are particularly simple if α is constant everywhere. Then $\nabla \cdot \boldsymbol{B} = 0$ is automatically fulfilled. A final simplification, a potential field, is obtained when α vanishes. Force-free and potential fields are uncoupled from the rest of the atmospheric parameters. Hence it is sufficient to know the field at the boundary of the computational domain in order to compute it in the whole volume. Conversely, this decoupling implies that force-free models can, by definition, not reproduce the thermodynamic properties of sunspots. They are unable to describe the relatively sharp boundary between the sunspot and the surrounding, almost field-free gas.

The magnetic field inside sunspots certainly comes close to being force-free in chromospheric and coronal layers due to the small gas pressure and density there. If small-scale structure is neglected then even a potential field provides a good description in these layers. In the photosphere this assumption is less secure since the energy density of the gas is actually larger than the energy density of the field in large parts of the sunspot.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Nevertheless, various models of the sunspot magnetic field based on the force-free or potential assumption have been constructed. Constant-α solutions approximately reproduce early observations of the radial dependence of the magnetic field strength, indicating that the constant-α approximation is adequate for the visible layers of simple sunspots.

Current-sheet models

The simplest consistent current-sheet model is composed of a flux tube in whose interior the magnetic field is potential, i.e. current-free, so that all the current is concentrated in a sheet at the boundary of the flux tube. This sharp boundary is termed the magnetopause. The main problem is the determination of the position of the boundary between the flux tube and the surroundings in the presence of arbitrary stratifications in the flux tube and its surroundings. An exact solution to this problem has, however, been found.

There are indications that a potential field bounded by a current sheet at the magnetopause is on its own inadequate to describe sunspots, in particular the presence of the penumbra. Far better agreement with the observations is obtained if this model is extended to include body currents, so that the field inside the sunspot is not purely potential, but is nevertheless surrounded by a current sheet. The body currents can be restricted to the radially outer part of the sunspot (corresponding approximately to the penumbra) and for the surface field to match the observations. It turns out that the field does not deviate greatly from potentiality anywhere (except at the boundary, of course) and is not self-similar.

Uncombed fields

On a small azimuthal scale horizontal field lines are observed to alternate with inclined ones in the penumbra. Various ideas have been proposed to explain the origin of these so-called fluted magnetic fields or uncombed magnetic fields. Basically these ideas consider the small-scale magnetic structure to be dynamic and its complexity to result from an instability.

One proposal for the source of the complex magnetic fine structure of the penumbra is due to the convective exchange of flux tubes. One possible scenario for interchange convection is the following: a flux tube near the magnetopause below the penumbra is heated by the field-free convective gas with which it comes into contact. The heated tube is buoyant and rises. At the surface it radiates away its excess energy, loses its buoyancy, becomes more horizontal and sinks again.

The first part of this scenario has been confirmed and quantified by 2D numerical simulations. An illustration is given in figure 3. A thin flux tube lying at the magnetopause (i.e. the outer boundary of the penumbra) heats up, becomes buoyant and begins to rise (the background penumbral field and gas, are stratified superadiabatically). The part of the flux tube near the outer boundary of the penumbra reaches the surface first. Below the surface the tube rises almost adiabatically, but above the surface radiative losses make it denser and reduce the buoyancy. Also, the background stratification is no longer superadiabatic. Consequently, the parts of the flux tube above the surface come to rest, staying horizontal, while the surrounding field remains strongly inclined. With time, parts of the flux tube ever closer to the umbra appear and lengthen the horizontal portion of the flux tube. The horizontal flux tube remains in equilibrium, since, for example, the negative buoyancy is balanced by the upward accelaration due to the expanding background field.

The part of the flux tube passing through the solar surface is filled with hot gas and appears bright, the other parts of the flux tube lying above the solar surface have had time to cool down and appear dark. Hence an observational signature of the formation of a horizontal flux tube is the movement of a bright point towards the umbra. Such moving bright points (called penumbral grains) have indeed been observed.

The other proposal starts with an inclined field and produces a horizontal field component by invoking a density inversion with height. To produce the density inversion a spatially localized impulsive upflow in the inclined magnetic component is postulated. In the almost vertical field of the umbra such an upflow is expected to be visible as an umbral dot. Note, however, that umbral dots do not show marked upflows, although it cannot be ruled out that such an upflow may be present, yet remain invisible in most spectral lines. In the penumbra, at a larger inclination of the field to the vertical, the flow, which fills a small flux tube up to a certain height, now causes dense material to overlie less dense material. A Rayleigh–Taylor instability develops which causes the filled flux tube to fall and become horizontal. Furthermore, the surplus material, which flowed up into the inclined flux tube, is now expected to flow outwards along the horizontal tube. A detailed numerical treatment of the collapse of a flux tube would be of great value to test this scenario, since the influence of curvature forces and the force acting on the flux tube due to the vertical gradient of the 'background field' of the penumbra has not been considered in detail as yet. These may well quench any instability from developing beyond the initial linear stage.

Brightness and thermal structure

Sunspot darkness

Biermann first proposed that the reduced brightness of sunspots is due to the inhibition of convective motions by the magnetic field. Since convection dominates energy transport below the observable layers, a quenching of convection turns a sunspot into an obstacle for the heat flux flowing outward through the convection zone. This leads to a diversion of energy away from the sunspot, which reduces the energy flux through the spot and produces a darkening. The diverted energy flux is mainly stored in the convection zone and released only over a time scale of 10^5 years, the time scale of the thermal adjustment

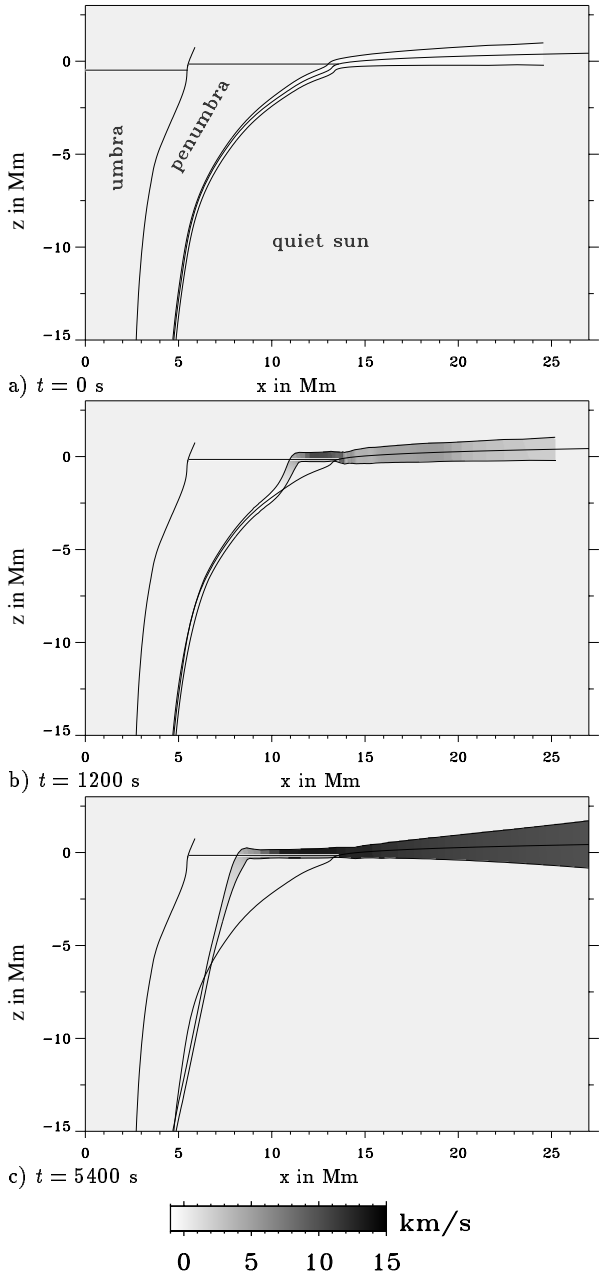

Figure 3. Vertical cut through a model penumbra. Vertical axis: height z, horizontal axis: radial distance x from the center of the sunspot (lying to the left). Indicated are the solar surface (horizontal lines near $z = 0$), the magnetopause between penumbra and quiet Sun and the current sheet between umbra and penumbra. Shown is the buoyancy-driven evolution of a flux tube starting at its initial location at the magnetopause until it lies partially horizontally at the surface. (From Schlichenmaier *et al* (1998) by permission.)

of the convection zone, which is much longer than the lifetime of a sunspot. Consequently, sunspots lead to a semipermanent darkening of the Sun. Due to the high lateral thermal conductivity of the gas in the convection zone, the diverted heat flux is distributed throughout the convection zone, so that no significant bright ring is expected around the sunspot. The convection zone also possesses a large heat capacity, which means that its temperature is raised only by an imperceptible amount. In the outer part of the solar interior convection is so much more efficient in transporting energy than radiation that a complete quenching of convection would reduce the heat flux so effectively that the question to ask in this case would not be why umbras and penumbras are so dark, but rather why they are so bright, in particular the penumbras. Therefore the inhibition of convection below sunspots is probably only partial.

Another proposal for explaining the darkness of sunspots is the deviation of the heat flux vector from the vertical due to the influence of the sunspot's magnetic field on the convection. Hoyle pointed out that it is mainly the motions across the field lines which are suppressed, so that the heat flux is channelled by the field. Its expansion with height leads to a dilution of the thermal flux. This effect on its own does not explain the observed umbral flux. It is nevertheless included in recent models.

Finally, Parker proposed that the heat flux is not diverted away from sunspots at all, but rather that umbras are actively cooled by the conversion of thermal energy into Alfvén waves. This mechanism now seems unlikely, since the expected flux of Alfvén waves is not observed.

Umbral brightness

Basically two approaches have been taken to solve the problem of too cool umbras. The first has been to form the sunspot out of a cluster of small flux tubes (spaghetti model) as initially proposed by Parker. Due to the tapered shape of each small flux tube, increasingly more field-free gas is present between them at increasing depth. Consequently, below the sunspot convection can penetrate relatively unhindered until close to the surface. In addition, for a sunspot composed of n small flux tubes the surface area of the side walls of the flux tubes, over which the convective gas can radiate into the magnetized gas, is $\sqrt{n}$ times larger than for a simple monolithic sunspot. A larger side-wall surface compared to the horizontal cross-sectional area leads to a much more efficient heating of the tubes (isolated small-scale tubes can have a bright bottom relative to the quiet Sun). This theory, like many other aspects of the cluster model, has not been quantitatively worked out in detail. If field-free material does penetrate to above the solar surface along unresolved hot columns then this could provide the missing radiative flux. Even if the individual small flux tubes carry no heat flux, then a 20% area coverage by the field-free columns would suffice to produce the observed flux. The columns would have to be very thin and numerous, however, since all parts of an umbra exhibit a minimum brightness. One advantage of this model is that it provides an explanation of bright umbral dots in the dark umbral background. They may

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

be considered to be intrusions of field-free material from below the solar surface into the photosphere.

The second proposal incorporates convective transport within a simple model of a monolithic sunspot (magnetoconvection). Such simulations are generally resticted to an initially homogeneous magnetic field in an idealized geometry and simplified equations (e.g. neglecting radiation) and often relate to plasma parameters far removed from those present in real sunspots. From a fully compressible calculation in an externally imposed vertical magnetic field it follows that the character of the convection below a sunspot umbra depends strongly on the parameter ζ, the ratio of magnetic diffusivity to thermal diffusivity. If $\zeta < 1$ then the convection is oscillatory, whereas if $\zeta > 1$ then the convection is overturning. At the surface $\zeta \approx 10^{-3} \ll 1$, but increases rapidly with depth, eventually becoming larger than unity. Therefore, the current picture is that oscillatory convection dominates in the 2000 km immediately below the surface, while the far more efficient overturning convection takes over in the deeper layers (depths of 2000–20000 km).

The two forms of convection are coupled through nonlinear interactions, so that hot convective plumes form which might penetrate right up to the surface. This coupled form of magnetoconvection is more efficient than purely oscillatory convection and conceivably could transport enough energy to explain the brightness of umbras even in a monolithic sunspot.

Another important parameter determining the nature of the magnetoconvection in these simulations is the Chandrasekhar number Q, which is proportional to the square of the imposed field. At sufficiently large Q convection is completely suppressed. As Q is reduced first weak, steady convection is excited, with isolated columns of rising gas and a continuous network of sinking fluid. When Q is lowered even further an oscillatory bifurcation sets in, with alternate plumes waxing and waning in antiphase. At still smaller Q the convection becomes more vigorous and chaotic, with the convective pattern changing rapidly. In all cases the convection introduces an inhomogeneity into the magnetic field. In the upper layers the field becomes concentrated in the downflowing network, while at greater depth there is a strong concentration below the upflowing plumes.

In most 'comprehensive' models of sunspots, i.e. models in which the force balance and energy equations are consistently solved for in the whole sunspot, the convective transport is treated by the mixing length formalism and the radiation by the diffusion approximation. The efficiency of the convective transport is varied by adapting the mixing length parameter $\lambda = l/H$, where l is the mixing length and H is the pressure scale height (e.g. Chitre 1963, Deinzer 1965, Chitre and Shaviv 1967, Yun 1970, Jahn 1989). Often even this approach is further simplified. For example, when combining the similarity assumption of the magnetic field with an energy equation, the thermal structure needs to be determined only along the axis of the symmetric sunspot and outside the sunspot. The horizontal variation of the temperature is fixed by the prescribed magnetic shape function. Hence the 2D problem of energy transport in an axially symmetric flux tube is reduced to a 1D problem.

One successful approach has been to solve both the force balance and energy equations in an iterative scheme. The latter includes radiative energy transport (in the diffusion approximation) and convective transport (in the mixing length approximation). The umbra and penumbra are treated separately, in that each has its own mixing length parameter λ, which is determined from the temperature gradient and is thus depth dependent. In addition, the volume below the umbra is assumed to be thermally isolated in the horizontal direction, so that the heat flux below the umbra is independent of depth. It turns out that in order to ensure a constant heat flux λ must increase rapidly with depth, being approximately 0.15 near the surface and reaching 0.7–0.8 at greater depths. For comparison $\lambda = 1$ describes the quiet Sun. A larger λ implies more efficient convection, so that the above result says that convection plays an increasingly important role relative to radiation with increasing depth below the umbra. This result is also consistent with the prediction of ζ going from $\ll 1$ to >1, since overturning convection is more effective than oscillatory convection. The small mixing length near the surface also agrees with the fact that the empirically derived temperature stratification at and just below the surface is close to radiative equilibrium.

Penumbral brightness

The above discussion has focused mainly on the umbra. The situation in the penumbra is rather different. The thermal flux through the penumbra is almost four times larger than in the umbra and three-quarters of that in the quiet Sun. Also, the field is far less vertical and less strong in the penumbra. It exhibits a prominent, radially elongated filamentary structure in white light, so that there is a rapid azimuthal variation of brightness. On average, however, there is a relative absence of a radial or azimuthal temperature gradient.

If the penumbra is thin, i.e. if the field lines lie roughly parallel to the solar surface and the magnetopause is located just below the surface everywhere in the penumbra, it is relatively easy to get a sufficient *energy* flux through the penumbra. Observations, however, suggest that over 50% of the *magnetic* flux of the sunspot emerges in the penumbra and field lines are considerably inclined to the horizontal there (by between 15 and 50°), signifying that the penumbra is thick (i.e. the magnetopause lies many scale-heights below the solar surface under most of the penumbra).

The heating of a thick penumbra requires some form of magnetoconvective energy transport. As in the case of the umbra, convection under the penumbra is often described by the mixing length formalism. Again, the mixing length must be reduced compared to the quiet Sun, but is larger than in the umbra. For example, models suggest that $\lambda \approx 0.7$ below the penumbra.

It is thought that most of the radiative flux emerging through the penumbra enters into the sunspot through the magnetopause. This feature is driven by the idea that most of the heat flux is transported from the magnetopause to the surface layers of the penumbra by interchange convection. Interchange convection is an inherently 3D process in which whole flux tubes rise and fall in the convectively unstable stratification below the penumbra. Below the solar surface the flux tube undergoes little heat exchange with its surroundings, so that it rises basically adiabatically. Hence, the gas trapped between the field lines of a rising flux tube has the heat content of the gas at the magnetopause. It has been suggesting that significant energy flows across the magnetopause only when it is inclined by more than a critical angle to the vertical. Depending on whether this condition is achieved or not a sunspot with penumbra (if the energy flows in from the sides) or a pore without a penumbra is formed.

Two-dimensional simulations confirm part of the interchange convection scenario. A flux tube lying along the magnetopause does indeed rise to the surface once it is heated sufficiently. It also brings hot gas to the surface, which then radiates away a part of its thermal energy. In contrast to the interchange convection scenario, however, the simulated flux tube does not sink back down again once it has cooled. This may be due to the simplifying assumptions underlying the simulations. For example, a more realistic treatment of the radiative transfer may lead to a more efficient cooling and allow the flux tube to sink below the surface again. On the other hand, the simulations do show that even after a flux tube has emerged and has been lying horizontally above the surface for some time, hot material keeps flowing up through its footpoint in the inner part of the penumbra. This upflow replenishes material that is flowing horizontally outwards along the tube. This horizontal outflow, which exhibits many of the properties of the Evershed flow, is driven by the excess of gas pressure at the inner footpoint, which is partly built up during the rise of the flux tube and is partly due to the higher temperature of the gas at the inner footpoint. The material emerging from the solar interior then flows towards the outer boundary of the sunspot, radiating away its excess heat on the way. This model reproduces the presence of bright penumbral grains and partly also bright and dark penumbral filaments, although according to it there is more bright material in the inner penumbra (i.e. near the umbra), which is not supported by observations. But the exact visibility of bright and dark filaments will need to be treated using proper radiative transfer before they can be compared quantitatively with observations.

Idealized simulations of convective modes in the presence of an imposed homogeneous field that is inclined to the vertical lead to waves travelling in the direction of the magnetic inclination. Both the strength and inclination of the field is affected by the waves.

Sunspot Oscillations and Seismology

Sunspots are known to host a wide variety of waves and oscillatory phenomena. The coupling between these oscillations and the 5 min acoustic oscillations of the surrounding quiet Sun provides a useful diagnostic probe of the magnetic and thermodynamic structure of the spot.

Oscillations in SUNSPOTS were first recorded during the period 1969–1972. The chief difficulty encountered in their detection is the suppression of the stray-light contribution to the oscillation signal from the surrounding quiet Sun. This contamination can be minimized by measuring Doppler velocities using molecular lines and low-excitation lines of neutral species with low ionization potentials, which form exclusively in the cool SUNSPOT UMBRA, or by measuring Doppler velocities using the polarized components of a Zeeman-sensitive line, which form only in a magnetized plasma (see POLARIMETRY).

Since sunspots are continuously jostled by the turbulent convection (GRANULATION) which surrounds them, it is probably no surprise that they host a diverse array of dynamic and oscillatory motions. It is an open question as to what fraction of the observed oscillations are the passive response of the sunspot to this external forcing, and what fraction are generated within the sunspot through magnetoconvection (see MAGNETOHYDRODYNAMICS: MAGNETOCONVECTION. It has also been recognized that the nature of these oscillations, coupled with the manner in which they are forced by the surrounding granulation and the solar acoustic oscillations (HELIOSEISMOLOGY), has the potential to reveal diagnostic information about the magnetic and thermodynamic structure of the subsurface sunspot interior (SUNSPOT MODELS). Thus, in more recent times, sunspot oscillations tend to be viewed in the broader context of *local helioseismology*, which emphasizes the connection between oscillatory wave fields inside and outside of sunspots.

Observations

For historical reasons, sunspot oscillations are broadly classified as falling into one of three categories:

- *5 min umbral oscillations* are large spatial scale (typically a substantial fraction of the entire umbra) coherent oscillations with periods between 250–400 s and root-mean-square (RMS) velocity amplitudes of 40–90 m s^{-1}, observed primarily in lines which form in the low SOLAR PHOTOSPHERE. The RMS amplitudes of these oscillations are roughly a factor of three smaller than typical pixel-by-pixel 5 min oscillation amplitudes observed in the surrounding quiet Sun. There is also a tendency for the spatial oscillation pattern to exhibit rapid radial propagation from the umbral center out through the SUNSPOT PENUMBRA with phase speeds of 50–100 km s^{-1}.
- *3 min umbral oscillations* are smaller spatial scale (3–4″) oscillations observed in lines which form in the upper photosphere and CHROMOSPHERE, with periods of order 140–200 s, and RMS velocity amplitudes of hundreds of meters per second in the mid-to-upper photosphere to several kilometers per second in the chromosphere. 'Saw-tooth' time series of Doppler velocities measured in chromospheric lines with peak amplitudes of several kilometers per second indicate that these oscillations are fully nonlinear throughout much of the chromosphere. Figure 1 illustrates the distinct observational character of the 5 min and 3 min umbral oscillations.
- *Running penumbral waves* are coherent outward-propagating wave arcs (subtending angles of 90–270°) readily observed in the penumbral chromosphere. The measured radial phase speeds of these waves vary between 8 and 35 km s^{-1}, with a tendency for the phase speed to decrease with increasing radial distance from the sunspot center. Typical Doppler motions associated with these waves are several hundred meters per second and the arc patterns repeat with a 200–300 s cadence. There is growing observational evidence that patchy downward extensions of these waves to the penumbral photosphere are present, but with radial phase speeds significantly greater than those measured in the penumbral chromosphere.

In all likelihood the distinctions between these three basic oscillatory motions are dictated more by observational issues than by clear physical effects. For example, when simultaneous umbral Dopplergrams are made in a number of spectral lines which cover a wide range of formation heights in the solar atmosphere, the detected oscillations exhibit both vertical and horizontal coherence *at the same frequency*, but are *incoherent* at distinct oscillation frequencies. Based on the coherence of the oscillations at different altitudes, phase lags can be determined. For frequencies below 5.2–5.5 mHz (the effective *acoustic cut-off frequency* for the umbral atmosphere), the oscillations are in phase at all overlying atmospheric levels, while for oscillations in excess of the acoustic cut-off frequency, a phase lag becomes more pronounced with increasing height separation. This behavior is generally interpreted as evidence for the upward propagation of waves for frequencies larger than 5.5 mHz. Indeed the 'saw-tooth' wave trains observed in the Ca II K-line may well be interpreted as the nonlinear steepening of these upward propagating waves due to the rapid decrease in density between the low photosphere and the mid-chromosphere.

Theory

Theoretical calculations of sunspot oscillations began in earnest in the mid-1970s, but have unfortunately not progressed much beyond the basic tenets of the initial models. The principal reason for this stagnation can be traced to the difficulties encountered in solving the relevant partial differential equations which describe the linear oscillations of a buried-dipole-type magnetic spot geometry (see figure 2 in SUNSPOT MODELS). If the magnetic field is *uniform* and aligned parallel (appropriate for the umbra), or perpendicular (appropriate for the penumbra),

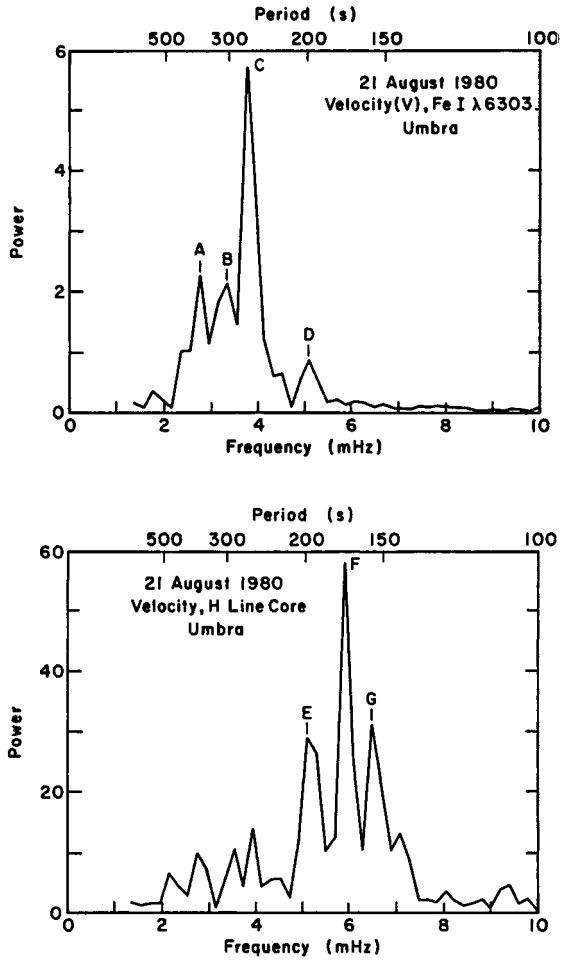

Figure 1. Temporal power spectra of the photospheric Doppler velocity (Fe I 630.3 nm: upper panel) and chromospheric Doppler velocity (Ca II 396.8 nm: lower panel), averaged over a single sunspot umbra. In the upper panel the photospheric oscillatory power is concentrated around periods of 5 min, while in the lower panel the power is greater by a factor of 10 and is shifted to shorter periods of 3 min at chromospheric levels. The precise locations of distinct power peaks, labeled A, B, C, . . . , are most likely an artifact of the spatial averaging of the point-by-point oscillation power spectra. Their numbers and locations are time variable within the same data set, and they are not reproducible between different observations. The peaks labeled D and E correspond to the same $P = 197$ s period, and their coincidence suggests a physical connection between the photospheric and chromospheric oscillations. (Adapted from Thomas *et al* 1984 *Astrophys. J.* **285** 368–80.)

to the prevailing atmospheric stratification, then these partial differential equations factor into a set of ordinary differential equations connected by several separation parameters—typically the horizontal wavevector $\boldsymbol{k}$ and the oscillation frequency ω. Hence, the somewhat artificial distinction between umbral and penumbral oscillations noted above is further maintained on the theoretical side of the problem. It is possible to extend the separation of variables technique to encompass uniform but arbitrarily inclined magnetic fields; however the results are not vastly different from those encountered for the purely vertical-field case.

When the uniform magnetic field has a component parallel to the stratification then the two characteristic wave propagation speeds—the adiabatic sound speed and the Alfvén speed—both vary with position along a given magnetic line of force. Consequently two of the three basic uniform MHD wave modes, the fast and slow magnetosonic waves, are coupled, while the Alfvén wave remains decoupled and propagates independently of them (see MAGNETOHYDRODYNAMIC WAVES). The mode-mixing between the slow and fast magnetosonic waves is minimal in the WKBJ limit (wavelength $\ll$ atmospheric scale height) or if the local sound and Alfvén speeds are of very different orders of magnitude, but neither of these regimes apply to the umbral photosphere. A large-scale global umbral oscillation mode may have *both* the character of the slow and fast magnetosonic waves for different local height ranges, as illustrated by figure 2. This mode mixing has important implications for seismic probing of spots.

A horizontal magnetic field, on the other hand, has a unique value of the sound and Alfvén speeds along each line of force. The variation of these characteristic propagation speeds with height leads to a different type of mode-mixing process known as *resonance absorption*. Unlike the more spatially diffuse mode-conversion process that applies in vertical magnetic fields, in a horizontal magnetic field the mode conversion is localized in the vicinity of a particular atmospheric layer, called a critical layer, where the local Alfvén or tube speeds match the projection of the phase speed of the atmospheric oscillation along the magnetic line(s) of force. Through this localized mode conversion, steep gradients and large amplitudes build within the critical layer until nonlinearities and/or dissipation cause the process to saturate or lead to secular evolution of the background atmosphere. Theoretical calculations employing strictly horizontal, or slightly inclined, magnetic fields have met with success in reproducing some features of the running penumbral waves. Clearly a better representation of all three types of sunspot oscillations awaits more sophisticated models which are capable of accommodating a smooth radial variation of the magnetic field inclination from the umbral core out to the periphery of the penumbra.

Seismology

It is possible to regard the interaction of ambient solar acoustic oscillations with a sunspot as a 'scattering experiment' of the sort familiar to physicists who employ high-energy particle beams to probe the structure of atoms, nuclei and elementary particles. In the sunspot 'scattering experiment' the incident acoustic 'beams' are produced in a haphazard manner by the surrounding quiet Sun, and as noted above, it is possible to detect oscillations within the 'target' sunspot proper. Three different 'experimental'

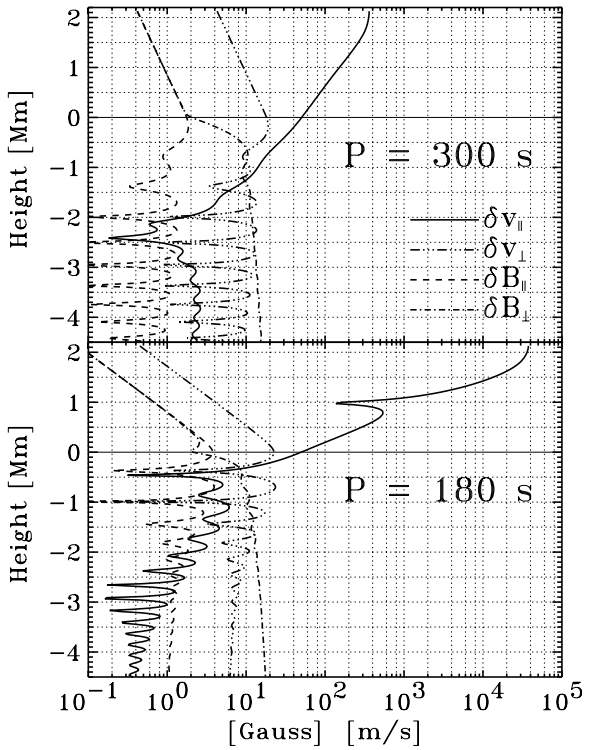

Figure 2. Typical examples of umbral oscillations computed for a uniform vertical 3000 G magnetic field imposed on a realistic sunspot model atmosphere. The four curves indicate the height variation of the RMS velocity and magnetic field fluctuations aligned with (∥), and perpendicular to (⊥), the magnetic field. The amplitudes of these two oscillatory modes are arbitrarily adjusted to yield an RMS Doppler velocity of 50 m s^{-1} at the base of the photosphere (height = 0 Mm). Notice the relative excess of Doppler velocities present in the chromosphere (+0.5 < height < +1.5 Mm) for the $P = 3$ min oscillation period relative to its $P = 5$ min oscillation period counterpart. This behavior is basically consistent with the observational data presented in figure 1. These vertical-field models suggest that a Doppler oscillation amplitude of 50 m s^{-1} translates into RMS magnetic fluctuations at the level of a few gauss. This is reasonably consistent with the current observational *upper limit* of 5–20 G for magnetic field intensity fluctuations in sunspot umbrae. (Adapted from Lites *et al* 1998 *Astrophys. J.* **497** 464–582.)

techniques for probing sunspot structure have evolved in parallel:

- *Frequency–wavenumber helioseismology* is closest in spirit to the particle physics approach since it relies exclusively on the oscillations observed in the quiet Sun surrounding the sunspot. This wave field is separated into waves with radially inward and radially outward senses of phase propagation, and each group is then further divided into its constituent frequencies (ω), horizontal wavenumbers (k), and azimuthal degrees (m). For identical values of (ω, k, m) one finds more power in the inward-propagating wave relative to its outward-propagating counterpart (by a factor of 1–3), and a positive phase shift of the outward- relative to the inward-propagating wave (0–150°). Broadly speaking these two findings suggest that sunspots absorb some of the acoustic oscillations, while the remainder that pass through the sunspot intact do so at somewhat greater propagation speeds than would apply in the surrounding quiet Sun.
- *Time–distance helioseismology* employs temporal cross-correlations of oscillation time series measured in the sunspot with those obtained in the surrounding quiet Sun at various radial distances (Δ). Inward- and outward-propagating waves are now distinguished by enhanced cross-correlations that appear at negative ($-\tau^-$) and positive ($+\tau^+$) time offsets, respectively, of the quiet Sun oscillation time series relative to the sunspot time series. For spots, $\tau^+ < \tau^-$, and the net 'travel time', $\tau^+ + \tau^-$, is less than the analogous value which obtains when the sunspot is absent (and for which the analogous positive and negative time offsets are *identical*). The smaller net 'travel time' for the spot relative to the quiet Sun is basically consistent with greater propagation speeds for waves inside the sunspot. The $\tau^+ \neq \tau^-$ directional asymmetry in the cross-correlation coherence maxima is more difficult to interpret. It could arise from coherent downflows beneath the sunspot, from time asymmetries due to dissipative process (absorption), or it could simply be a consequence of observational (spatial and temporal) peculiarities associated with the detection of the sunspot oscillations.
- *Acoustic holography* carries the concepts of time–distance helioseismology one step further through the 'acoustical imaging' of the subsurface environment of a spot. For each subsurface 'focal point', an *egression* of the wave field recorded at the solar photosphere is carried out. The egression effectively discards that portion of the wave field which is not consistent with the signature of an acoustic point source located at the specified focal point. Maps of the RMS egression computed for a subsurface volume over a specified period of time show that a relative egression deficit ($\leq$50%) is present below sunspots. The horizontal extent of the deficit region is about twice the visual extent of the spot.

Beyond general indications of increased propagation speeds and acoustic absorption implied by the findings noted above, the extant body of theoretical work interpreting these robust observational results must be viewed as highly speculative and subject to future revision. Any program to simultaneously model oscillations within, and outside of, a sunspot must be based upon a non-trivial sunspot equilibrium model with *non*uniform magnetic fields. This entails the difficult task of solving the partial differential equations which govern the sunspot oscillations *and* connecting these oscillations with those in the neighboring quiet Sun. Various attempts aimed at circumventing this complicated problem through the reliance on ray theory, or its variants, which all derive

from the WKBJ formalism, run afoul of the acoustic analog of Heisenberg's uncertainty principle. Recall that the spatial and temporal extent of a wave packet is inversely proportional to the range of wavenumbers and frequencies of the constituent waves from which the packet is composed. The distribution of observed oscillatory power across the k–ω diagram (see figure 4 in HELIOSEISMIC OBSERVATIONS) necessarily imposes fundamental limitations upon how sharp a ray bundle can be, and for the most part, sunspots are probably too small to safely treat their interaction with acoustic oscillations in the 'geometrical-acoustics' limit.

With these caveats in mind, preliminary work does suggest that the mode conversion of the forcing acoustic oscillation to magnetic-field-guided slow magnetosonic waves, and resonance absorption in critical layers, may play crucial roles in accounting for the deficit of outward- to inward-going waves in the sunspot environment.

Sunspot Penumbra: Structure and Activity

As viewed in white light, a sunspot consists of the dark, central umbra surrounded by the brighter, radially striated penumbra. The structure of the penumbra is generally more complicated that that of the umbra, and our understanding of penumbral structure has developed slowly as observations have provided us with increasing spatial resolution.

The relative darkness of sunspots is attributed to the inhibiting effect of the spot's magnetic field on the convective transport of heat. The inhibition of convection is quite strong in the umbra, which transmits only about 20% of the average solar heat flux. In the penumbra, however, the convection is far more efficient, with the penumbra transmitting some 75% of the average heat flux with a radial variation of less than 5%.

The radial striations in the penumbra seen by early observers were resolved as alternating bright and dark filaments by the balloon-borne Stratoscope in the late 1950s. Subsequent high-resolution observations, especially at Pic du Midi, showed that the bright filaments consist of several elongated grains which migrate inwards toward the umbra. Some of these bright grains penetrate into the umbra and form the peripheral umbral dots in the umbra (see also SUNSPOT UMBRA: STRUCTURE AND ACTIVITY). Fully resolving the fine structure in the penumbra poses a real challenge for modern high-resolution observing techniques (see figure 1). The power spectrum of intensity fluctuations is fairly flat down to wavelengths at the current limit of angular resolution (about 0.2 arcsec), implying that there is a considerable amount of smaller fine structure yet to be resolved.

In Hα the penumbra also displays a filamentary structure, but at this higher level in the atmosphere the so-called superpenumbra extends radially much further outward, to distances as much as twice the sunspot's radius in white light. In the corona, as seen in x-rays, filamentary features emanating from the inner penumbra extend much further outward, to distances comparable with the solar radius. The filamentary structure of the penumbra is intimately associated with the structure of the sunspot's magnetic field.

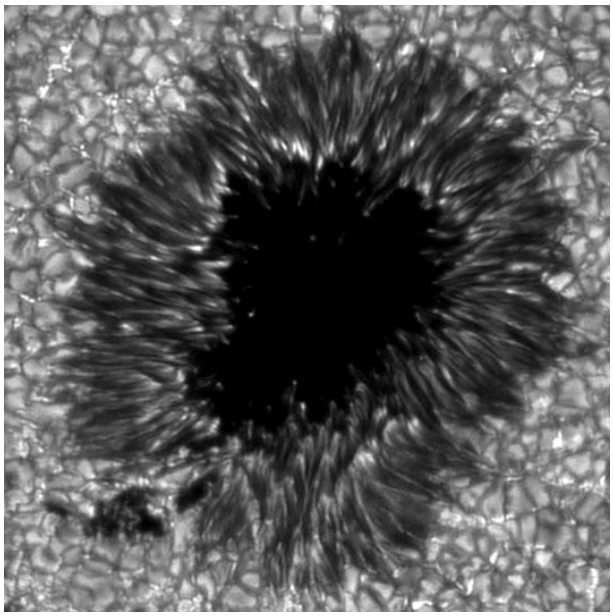

Figure 1. High-resolution image of a sunspot taken in May 1998 with a G-band interference filter (1.2 nm bandpass centered at 430.5 nm) at the Swedish Vacuum Solar Telescope on La Palma, showing the bright and dark penumbral filaments and the bright grains that constitute the bright filaments. Some of the bright grains extend well into the umbra. The normal solar granulation pattern occurs outside the sunspot; the bright points in the intergranular lanes correspond to intense magnetic flux tubes emerging from the solar surface. (Courtesy of T Berger, Lockheed-Martin Solar and Astrophysics Laboratory).

The magnetic field in the penumbra

The mean (azimuthally averaged) magnetic field in a sunspot at the solar surface is vertical at the center of the umbra but flares outward so that the mean field is inclined at about 20° to the horizontal at the outer edge of the penumbra. The strength of the mean magnetic field decreases monotonically with radial distance from the center of the sunspot, dropping by a factor of 2 or 3 at the outer edge of the penumbra. Typical magnetic field strengths are 3000 G in the center of the umbra and 1000 G near the outer edge of the penumbra.

The detailed geometry of the magnetic field in the penumbra is far more complicated than that of the axisymmetric mean field discussed above, and indeed a clear picture has emerged only in the last decade (see also SUNSPOT MAGNETIC FIELDS). Formerly it was thought that the penumbra is a rather shallow structure formed by magnetic field lines emerging through the solar surface in the outer umbra and bending over sharply to lie horizontally along the solar surface. In this picture, very little magnetic flux actually emerges through the solar surface within the penumbra. Now, however, we know that the penumbra is a deep structure in which a significant fraction, more than half, of the sunspot's magnetic flux emerges through the surface.

Observations by Beckers and Schröter at Sacramento Peak in the 1960s suggested that, while the magnetic field in the dark filaments is nearly horizontal (relative to the solar surface), the field in the bright filaments is significantly inclined to the horizontal. More recently, high-resolution spectroscopy and precision polarimetry have revealed a 'fluted' or 'corrugated' structure of the penumbral magnetic field, with the inclination of the field varying azimuthally around the sunspot (see figure 2). In the outer penumbra, the inclination to the horizontal varies from 0° in the dark filaments to 35°–40° in the bright filaments, giving a mean inclination of 15°–20°. In the inner penumbra, the mean inclination is about 45° with azimuthal fluctuations of ±15°–20°. The magnetic

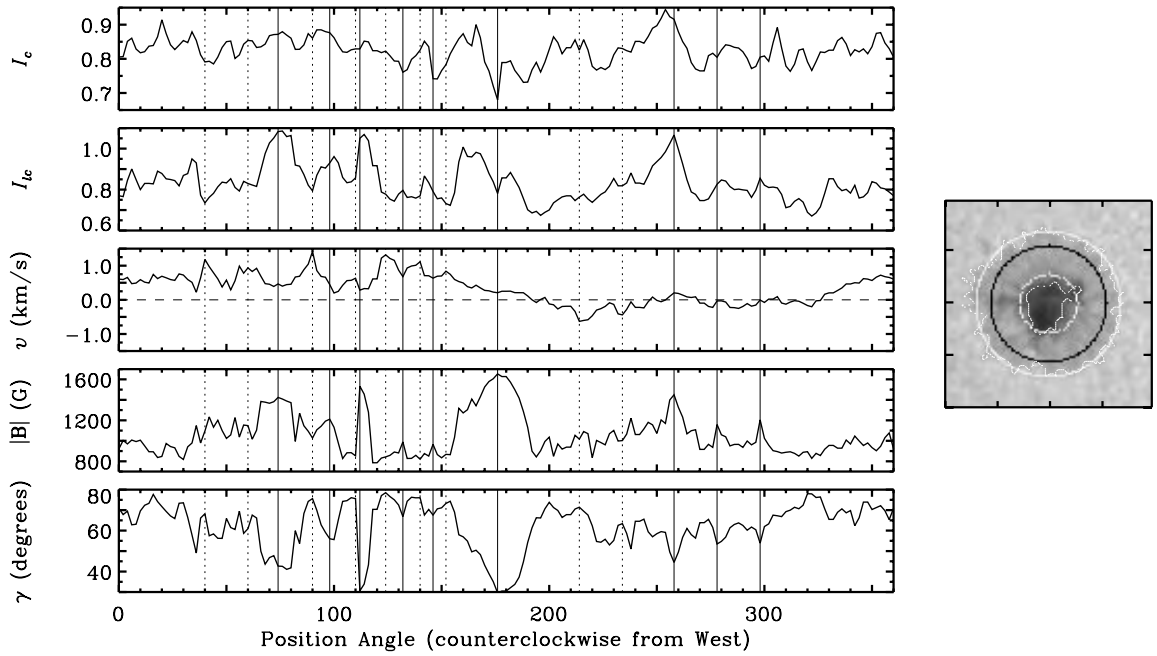

Figure 2. The azimuthal variation of several quantities around a circle (shown in black on the continuum image) in the outer penumbra of radius $0.8R$, where R is the radius of the circle that just contains the entire penumbra (the outer white circle). Shown here are the variations of magnetic field strength $|\boldsymbol{B}|$, zenith angle γ of the magnetic field, line-of-sight Doppler velocity v (in Fe I 630.25), continuum intensity I_c and line core intensity I_{lc} (in Fe I 630.25) with position angle (in degrees, measured counterclockwise from solar west). The solid vertical lines mark the locations of significant local maxima in the field strength $|\boldsymbol{B}|$; note the strong anticorrelation between field strength and inclination angle in the 'fluted' penumbra. The dotted vertical lines mark the locations of significant local maxima of the magnitude of the Doppler (Evershed) flow velocity, $|v|$; note that these flow channels generally coincide with lower intensity (especially line core intensity I_{lc}) and nearly horizontal magnetic field. (From Stanchfield *et al* (1997).)

field strength is somewhat weaker where the field is more nearly horizontal. The radial 'spines' of stronger, more inclined magnetic field account for most of the emerging magnetic flux in the penumbra.

Motions in the penumbra

Observations of persistent motions in the penumbra show systematic inward proper motions (toward the umbra) of the bright elements in the inner penumbra, while in the outer penumbra the dominant motion is the outward Evershed flow occurring mostly in the dark filaments.

The most readily apparent motion in the penumbra is the radial, nearly horizontal outflow of gas responsible for the Evershed effect seen in spectral lines formed in the penumbral photosphere (see SUNSPOTS: EVERSHED EFFECT). The flow is generally concentrated in the dark penumbral filaments, where the magnetic field is more nearly horizontal, and is directed along the magnetic field lines (see figure 2). This motion is thought to be a siphon flow driven by a pressure difference between the footpoints of arched magnetic flux tubes. This mechanism has only recently been confirmed by high-resolution observations showing the magnetic field lines and flow diving below the solar surface near the outer edge of the penumbra. The siphon flow mechanism is probably also responsible for the reversed, inward Evershed flow of gas seen higher up in the penumbral atmosphere, in chromospheric spectral lines such as Hα.

A sunspot penumbra exhibits a range of interesting wave motions (see SUNSPOT OSCILLATIONS AND SEISMOLOGY). The most conspicuous of these waves are the running penumbral waves seen in Hα. These consist of dark wavefronts in the form of concentric arcs, sometimes extending nearly all the way around the umbra, originating at the umbra–penumbra boundary and propagating radially outward across the penumbra at speeds of 10–20 km s^{-1}, and repeating with a period in the range 200–300 s. The high propagation speeds, well above the local sound speed, indicate that these penumbral waves are largely magnetic in character. The running penumbral waves may be related to umbral oscillations, but the connection is not really clear. Compared with the chromospheric umbral oscillations, the running penumbral waves are much less energetic, having velocity amplitude of only some 200 m s^{-1} at the base of the chromosphere (at the temperature minimum) and 1 km s^{-1} in the chromosphere (at the height of formation of Hα). Other oscillatory motions in the penumbral photosphere, with periods around 5 min, are related to the interaction of the sunspot with the resonant acoustic modes (p-modes) in the surrounding quiet Sun.

On longer time scales, on the order of a half hour, there occur slow convective interchange motions of magnetic flux tubes. These motions are responsible for the bright and dark penumbral filaments, the fluted geometry of the penumbral magnetic field, and the vertical heat transport in the penumbra. Magnetic flux tubes that initially lie along the outer surface of the sunspot's sheaf of magnetic field, in contact with the hotter surroundings, are heated, become more buoyant, and rise upward, carrying excess heat and appearing bright. The footpoints of these rising inclined flux tubes, where the tubes emerge at the solar surface, migrate inward producing the inward-moving bright grains. Meanwhile, the rising, heated flux tubes are replaced by descending, cooler flux tubes (in the dark filaments) which, on reaching the outer boundary, are in turn heated. This interchange process repeats itself continually, producing the quasi-steady vertical transport of heat responsible for the penumbra's relative brightness compared to the umbra.

The formation of a penumbra

Magnetic flux in emerging active regions first appears in the form of SUNSPOT PORES, which then may coalesce to form sunspots. A sunspot is distinguished from a pore by having a penumbra. The formation of a penumbra is apparently the result of a sudden transition in the structure of the accumulated magnetic field, from a bundle of nearly vertical field lines to a widely fanning sheaf of field lines with nearly vertical field in the umbra and nearly horizontal field in the penumbra. This transition between a pore and a sunspot, as the amount of accumulated magnetic flux increases, is a complicated nonlinear process involving the onset of overturning magnetoconvection at the outer edge of the pore (see MAGNETOHYDRODYNAMICS: MAGNETOCONVECTION). Although sunspots are generally larger than pores, there are pores as large as 3.5 Mm in radius and sunspots (with rudimentary penumbrae) as small as 1.8 Mm in radius. Our understanding of this situation is that, if we consider the radius as a function of total magnetic flux, there are two families of stable solutions which overlap at intermediate radii. The transition between the two states occurs when filamentary convection sets in suddenly to form a penumbra at the outer edge of the pore, where the magnetic field becomes more nearly horizontal with increasing total magnetic flux. In the language of nonlinear systems, the pore solution loses stability at a saddle-node bifurcation.

Sunspot Pores

Basic properties of pores

Pores are, roughly speaking, small SUNSPOTS without a clear penumbra (see SUNSPOT PENUMBRA). While the visual appearance of a sunspot is that of a very dark central umbra surrounded by a filamentary annular penumbra, a pore is a fairly uniform dark spot on the solar disk. Like sunspots, they are the surface manifestation of strongly magnetized tubes permeating the visible solar surface layers or SOLAR PHOTOSPHERE. Their diameter in continuum images is typically only a few (2–4) thousand kilometers and they appear for hours to a couple of days at most. Their surface magnetic field is of the order of 1000–2000 G (the Earth's magnetic field is about 0.4 G). In contrast, a sunspot can easily be 10 times larger in size and can exist for weeks or months, while the magnetic field in the centre of a sunspot umbra can be twice as large.

The distinctive property of pores is the associated darkening in photospheric intensity. Using the morphological definition that labels pores as those magnetic structures that lack an observable penumbra, the size distribution of pores and sunspots overlap. The largest pores (3–4 Mm radius judged from their continuum appearance) may suddenly form a partial penumbra, turning them into sunspots. Both observational and theoretical arguments support a scenario for penumbra formation when a critical size and field strength is exceeded. The transition would take place at a total magnetic flux of order 10^{20} Mx (Mx, Maxwell, defined as 10^{16} Mx $= 1$ GMm^2). In that sense, pores are just a phase in the build-up towards a stable mature sunspot. Emerging magnetic flux in an ACTIVE REGION rapidly organizes itself into pores, which may gather to organize themselves into a sunspot. A similar process acts to form a single pore: magnetic elements (250 km diameter flux tubes with 1–2 kG fields) coalesce somewhat spontaneously to form a pore. Individual magnetic elements of size $\sim$200 km diameter have been observed and constitute up to 90% of the net magnetic flux outside sunspots and pores. Within several hours, pores can evolve in size, form or disappear, so they are truly transient sunspots.

Formation scenario

As a rule, pores develop in very young active regions. Figure 1 shows a close-up view of the solar photospheric layers in continuum intensity. Shown is an area of 48.12 square arcseconds of the solar surface as seen at a wavelength of 6708 Å. This continuum image was obtained with the Swedish Vacuum Solar Telescope (La Palma, Spain) on 10 May 1994. The GRANULATION pattern of bright cellular patches separated by darker and cooler lanes is seen all over the solar surface, while the three black spots are pores. The granulation represents the uppermost layer of the solar convection zone (see SOLAR INTERIOR: CONVECTION ZONE), the superadiabatically stratified outer 30% of the solar envelope. The mean distance between the bright granule centers is 1.5–2 Mm. Hence, the size of the pores in the figure varies from 1 Mm diameter for the smallest one to 3–4 Mm for the largest. Clearly, their shape can be very irregular, but they are fairly stable structures compared with the surrounding granulation pattern. The bright granules typically last for 16 min or so, while (large) pores can exist for days. Figure 1 is of exceptional quality, since hints of internal structure, reminiscent of umbral dots (see SUNSPOT UMBRA) can be detected in the largest pore shown. A clear discussion of the fine structure in pores can be found in Bonet *et al* (1995). They observed pores on the Sun during a partial solar eclipse, which allowed them to correct precisely for the seeing degradation induced by the telescope and the atmosphere of the earth.

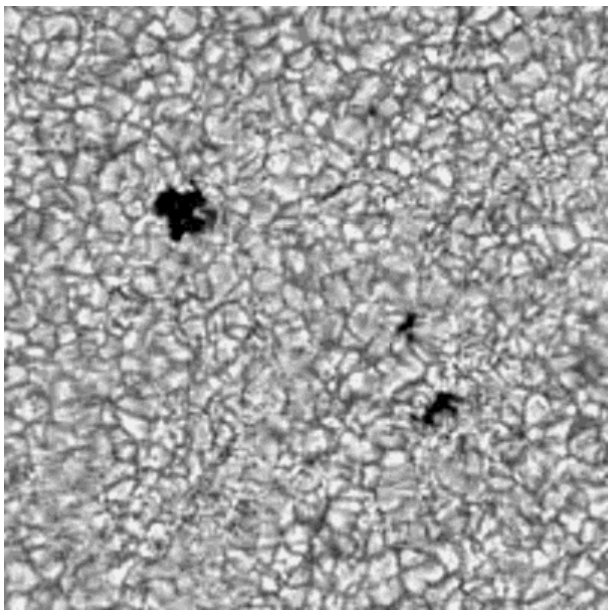

Figure 1. Pores seen on the solar disk in white light. The area shown is approximately 35 Mm $\times$ 35 Mm. Figure courtesy of V Martínez Pillet.

While ideally a pore is thought of as a monolithic tubular entity, it likely consists of a collection of even smaller magnetic elements. These ought to be tightly packed and linked deeper down as one magnetic trunk (Martínez Pillet 1997). A scenario for the formation of strongly magnetized 'trunks' is as follows. Large-scale flow fields tend to concentrate the magnetic field at the photosphere into the intergranular lanes. There, magnetic elements and even small pores may form due to a convective collapse. Thereby, a downflow in a magnetized tube accelerates. As a result, the tube evacuates, which in turn leads to a transverse amplification of the field. The resulting 1–2 kG magnetic fibrils are then constantly buffeted by the large convective cells. Converging flow fields in the local granular or meso-granular convection pattern could draw several magnetic elements together and form the larger pores. The surrounding downflow adds to the stability of the structure. The accumulated magnetic flux will eventually affect the local magnetoconvection pattern and darken (see MAGNETOHYDRODYNAMICS: MAGNETOCONVECTION).

Keppens and Martínez Pillet (1996) reported the detection of pore formation, associated with a 5% continuum contrast, as soon as the magnetic flux reaches (4–5)$\times 10^{19}$ Mx within a 1.5 Mm radius.

Temperature structure

A statistical survey reports few or no pores close to the solar limb. This is surely associated with the identification of pores as dark structures compared to their surroundings. Their internal vertical temperature stratification can change their visual appearance from dark and cool at the disk center to invisible or brighter than the ambient atmosphere at the limb. Continuum observations towards the limb actually sample higher layers, so that one really needs to determine the two-dimensional (assuming axisymmetry in the third dimension) temperature structure of a solar pore. Sütterlin (1998) presents such a detailed analysis which confirms that the temperature difference between the pore center and surroundings drops with height and may even reverse for small pores. Figure 2 shows the inferred temperature structure as a function of height and radial distance for a pore with a 3.2 Mm continuum diameter (taken from Sütterlin 1998). The temperature range is indicated in kelvin on top. Equally important in Sütterlin's study is the determination of the Wilson depression across the pore, which is the geometrical height from which most continuum radiation escapes freely (optical depth $\tau = 1$). For the pore in figure 2, the $\tau = 1$ surface varied by 200 km across the pore.

Although it is difficult to assess the influence of stray light in the continuum intensity of a pore, it has been established that the radial variation of the brightness in pores is a smooth increase towards its rim. This is quite different in sunspots, where the continuum appearance is that of a very dark central umbral region, surrounded by a plateau of a brighter, more filamentary penumbral annulus. The central region of a pore is darker and hence, cooler, for larger pores. In cases where a sunspot forms, the original pore remains as the umbra.

Magnetic structure of pores

The strong magnetic field in pores is immediately responsible for their darkness relative to the surrounding photosphere. When a significant amount of flux is accumulated within a 1.5 Mm radius, this area darkens (cools) and turns into a pore. Indeed, a sufficiently bundled and localized kG magnetic field will disturb the outward convective energy transport towards the solar visible surface layers, thus forming the cooler pore. The value of the field strength can be determined from magnetically sensitive absorption line spectra. Polarimetric measurements of, for example Fe I lines, are now routinely used to derive the vector magnetic field in sunspots, pores and plage regions. The strong magnetic fields lift degeneracies in the atomic levels of the ions. Stokes polarimetry uses the resulting wavelength variation of the intensity, the net circular and both net

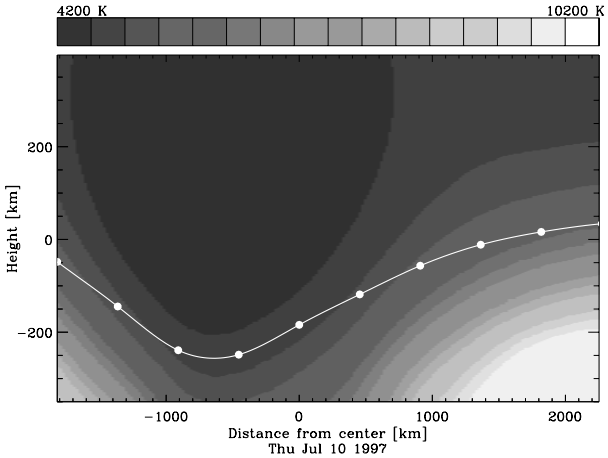

Figure 2. The two-dimensional temperature structure of a pore. The white line indicates the $\tau = 1$ surface. Figure courtesy of P Sütterlin.

linear polarization effects to determine the magnetic field strength, the inclination of the field to the local vertical and its azimuth. This inversion process involves the tuning of parameters representing the magnetic and thermodynamic atmosphere until the profiles closely agree with the ones observed. In this way, one can construct magnetic maps of the solar surface giving the full 3D structure of the field. In such maps, sunspots and pores are readily identified as coherent, strongly magnetized structures. In maps of magnetic field azimuth angle, they both show a well-defined center about which a full 360° range in angle is observed. Keppens and Martínez Pillet (1996) selected magnetic features from azimuth maps and inferred their magnetic radii. These magnetic structures do not always correspond to a continuum dark spot like a pore or sunspot. Azimuth centers without pronounced continuum contrast were termed 'ACs' and these ACs sometimes evolve in a pore within a time span of hours.

Statistics on a sample of 51 pores showed that their magnetic extent is always larger than their continuum appearance. Whether or not this is to be attributed to the existence of a magnetic canopy surrounding the pore proper is unclear. Martínez Pillet (1997) proposed a cartoon pore model consisting of a densely packed dark central part with an outer rim of magnetic elements linked together subsurfacely. Since loosely spaced magnetic elements insufficiently inhibit convective energy transport, a pore then merely seems smaller judged from continuum images alone. Only pore seismology, combined with high-resolution polarimetric observations in infrared wavelengths (which probe deeper layers than the Fe I lines) may tell us whether this is indeed the case.

To determine the magnetic structure across a typical pore, Keppens and Martínez Pillet (1996) calculated sample mean radial profiles of the azimuthally averaged magnetic field. In particular, since each pore in their sample had a readily identifiable azimuth center,

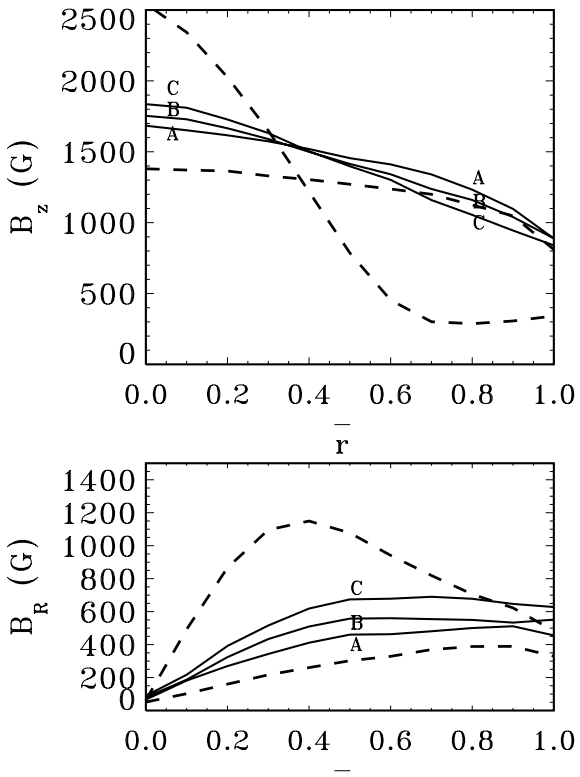

Figure 3. The magnetic structure of pores compared with sunspot magnetic fields.

averaging the 3D field structure about this center gives reliable information on the vertical and radial field structure. Grouping the 51 pore sample in three subgroups A, B and C of increasingly larger pores, the variation of the field structure with size could be deduced. The same procedure was used to obtain radial profiles for a typical sunspot, and for the ACs (those magnetic structures clearly detected in azimuth maps without a clear continuum contrast, believed to be candidates for pore formation). The results in figure 3 show the vertical magnetic field components in the top panel, and the radial ones in the bottom panel. The virtually horizontal dashed curves correspond to the sample of ACs, which are seen to be purely vertical magnetic structures or flux tubes. Their maximal field strength is roughly 1400 G. The plot confirms that for pores of increasing size (from A to C), the central field strength increases from 1700 to 1900 G. Therefore, a clear correlation between pore size, continuum intensity and magnetic field strength exists. Note further how figure 3 indicates that pores are still fairly vertical structures (the average inclination at the edge derived from the sample was found to be 35°), but a tendency to fan open with size is also evident. The largest variation of the field structure is found for sunspots (dashed curves), where interestingly, the penumbra boundary coincides with a 40–45° inclination so that the azimuthally averaged penumbral field is primarily horizontal, while it is almost vertical in a sunspot umbra.

This suggests that when the field inclination at the edge of a stable magnetic structure increases beyond 40–45°, the concave tube boundary may be susceptible to a fluting or interchange instability, thereby fragmenting its boundary and forming a filamentary, predominantly horizontal 'penumbra'. In fact, the dynamic and fibril nature of a sunspot penumbra suggests that the instability is convective in nature. That a semistable horizontal penumbra should eventually form could be expected from the stabilizing influence of buoyancy, acting at sufficiently strong inclination. An observational clue to this process was presented by Keppens and Martínez Pillet (1996), where part of a large pore showed an appreciable change in its continuum intensity within a few hours. Analysing the magnetic field evolution in time, the magnetic structure changed from almost vertical throughout, to a two-component structure very much like a typical sunspot. More observations of higher spatial and temporal resolution of evolving large pores are needed to confirm this scenario. It is thereby vital to have simultaneous continuum and polarimetric measurements.

More measurements of the field inclination in pores seem warranted, to test the hypothesis of penumbra formation when a critical angle is exceeded. This scenario has been investigated by Rucklidge *et al* (1995). They constructed pore and sunspot models taking into account flux conservation and a balance between surface emitted energy and the energy entering laterally and from below. In solution diagrams of spot size versus magnetic flux, pores and sunspots form distinct curves which overlap in their size range, as observed. The pore solutions lose stability at a bifurcation point, indicating the onset of a penumbral filamentary convection as soon as the edge field tilted beyond a critical angle (taken at 45°). Beyond this inclination, the energy balance dictated the need for convective transport across the magnetopause into the flux tube. Observations reveal that the field inclination in pores varies almost linearly with radial distance from the center. Edge values up to 60° with respect to the surface normal have been reported (Sütterlin 1998), comparable to inclinations for the bright filaments in a sunspot penumbra (the dark ones are nearly horizontal). The statistical analysis by Keppens and Martínez Pillet (1996) found a mean inclination of 35° at the magnetic edge of the pore, after azimuthal averaging. The main difference results presumably from the underlying model used in the inversion procedure. Although both inversion codes used a set of eleven parameters to determine the emergent Stokes vector, Sütterlin (1998) emphasizes the two-dimensional temperature structure. He included parameters related to the vertical thermodynamic (and magnetic) variations. Lites and Skumanich (1990) consider all thermal, magnetic and dynamic quantities as constant through the line forming region, except for the linear τ-dependence of the source function. In this respect, the variation of the Wilson depression as shown in figure 2

has consequences for interpreting the vector magnetic field data. Determinations of the vertical field gradient in pores quote values around $\mathrm{d}B/\mathrm{d}z = -4\,\mathrm{G\,km^{-1}}$.

Pore models and wave modes

Since pores are rather stable compared with the shortlived granules around them, models try to mimick a magnetohydrostatic balance in stratified, radiating surroundings. First modeling efforts used potential field solutions neglecting stratification and radiation. Models like those by Rucklidge *et al* (1995) concentrate on the connection between pores and sunspots by penumbra formation. Full modeling is difficult when accounting for both the superadiabatically stratified convective surroundings and the transition to the optically thin regime. Two-dimensional time-dependent numerical simulations of magnetic elements and pores in non-stationary, radiative convection show that the smaller magnetic structures are strongly influenced dynamically. The photospheric indications of fine structure in pores also tell us that full three-dimensional modeling of magnetoconvection is required.

Due to the dynamic surroundings, MAGNETOHYDRODYNAMIC WAVE modes of all types are continuously excited in pores. The study of wave modes of and wave interactions with flux tubes is a subject in its own right. For small, stratified magnetic flux tubes, the wave modes can be studied by neglecting their radial variation. For the larger structures, this radial variation can no longer be ignored. Wave modes of purely radially stratified magnetic flux tubes embedded in wave-carrying surroundings can describe their linear dynamics satisfactorily. Radial variations across the primarily vertical magnetic field allow for localized wave heating. For magnetic elements, one-dimensional studies of this process indicated that slow resonant absorption can be acting in a layer 400 km above $\tau = 1$. In general, both radial and vertical gradients play an important role in the interaction (see SUNSPOT OSCILLATIONS AND SEISMOLOGY). Numerical simulations of wave interactions with a stratified vertical field showed how impinging P-MODES can also be converted to slow magneto-atmospheric-gravity waves, ducted along the field lines. The study of linear wave modes yields invaluable insight for the nonlinear numerical simulations where the truly dynamic nature of the smaller magnetic structures is evident.

Pore seismology?

A scenario for pore formation by packing magnetic elements in a bundle raises the question whether a pore, once formed, is a monolithic or fibril structure. Also, the suggested subsurface appearance as a larger magnetic trunk should be deduced from observations. Attempts to answer such questions for sunspots make use of the indirect sampling of the sunspot by impinging p-modes. It has been noted that a fibril structure can be more efficient in extracting the incident power since multiple scattering ensures that the exciting waves revisit the sites of energy loss, and the losses add coherently. Large pores can be sampled by techniques developed in sunspot and active region seismology. The way pores form suggests a fibril model which indicates they could be efficient sinks of p-mode energy. Such studies will be hampered by the fairly rapid evolution and the short lifetime of pores. Moreover, due to their size and intrinsic field strengths, they may not correspond to sufficiently strong scatterers of acoustic wave energy. However, a full three-dimensional reconstruction of the pore structure would give valuable indications of the possible scenarios for the onset of penumbra formation.

Conclusions

Since the size of the smallest pores and the magnetic elements is comparable to the best obtainable resolution to date, efforts to deduce their three-dimensional composition as well as their dynamic properties will continue. Model simulations should address the details of pore formation and stability. The link between magnetic structures of all sizes is still an issue worth studying. Ultimately, this will help unravel the relation between the surface manifestation of the solar magnetic field and the way in which this field is generated and evolves subsurfacely. Pore formation and coalesence represent the first clear visual clues to the emergence of large Ω-shaped flux loops. Simulations have confirmed the possibilities for storing and amplifying enormous toroidal flux ropes in the overshoot region below the convection zone. They can rise through the convection zone and finally erupt in a tree structure to lead to the surface active region development. The determination of the atmospheric and magnetic conditions prevailing in pores may guide the required modeling of this eruption phase.

Sunspot Umbra: Structure and Evolution

Sunspots show two main structures: a central dark region, the umbra, surrounded by a brighter and filamentary zone, the SUNSPOT PENUMBRA (see figure 1 in the article on SUNSPOT EVOLUTION). Sunspots without penumbra are usually called SUNSPOT PORES. Observed with low spatial resolution, the umbra appears homogeneous. However, even by the nineteenth century astronomers were able to detect fine details. In fact all the structures mentioned below were observed at that time. The names of Secchi, Janssen and Chevalier should be mentioned in this context.

An important development in our knowledge of the fine structure of sunspots occurred in the 1960s with the balloon observations of the Stratoscope Project (M Schwarzschild at Princeton University) and with ground-based observations reported in the monograph of Bray and Loughhead (1967). However, the low dynamic range of the photographic plates available at that time did not allow reliable photometric measurements of the fine details inside the umbra to be made. In recent times the use of CCD cameras has solved this problem. The application of image-selection techniques at observatories with excellent atmospheric conditions (Pic du Midi, Sacramento Peak, Tenerife and La Palma) has enabled time series of sunspot images to be obtained at very high spatial resolution ($\approx 0.3''$). In the near future, the application of two-dimensional spectropolarimetric and image reconstruction (speckle interferometry, phase diversity) techniques will improve our knowledge of these features yet further.

Very often the umbras of individual sunpots within a group are divided into different parts by a bright structure known as a light bridge (hereafter LB). We will call these individual umbras umbral cores (UCs). A schematic view of the detailed structures observed in sunspot umbras is shown in figure 1.

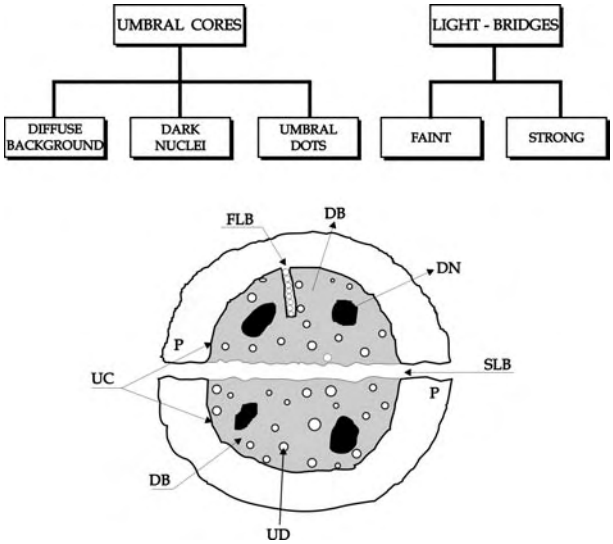

Figure 1. A chart and an idealized scheme showing the different fine structures visible in sunspot umbras.

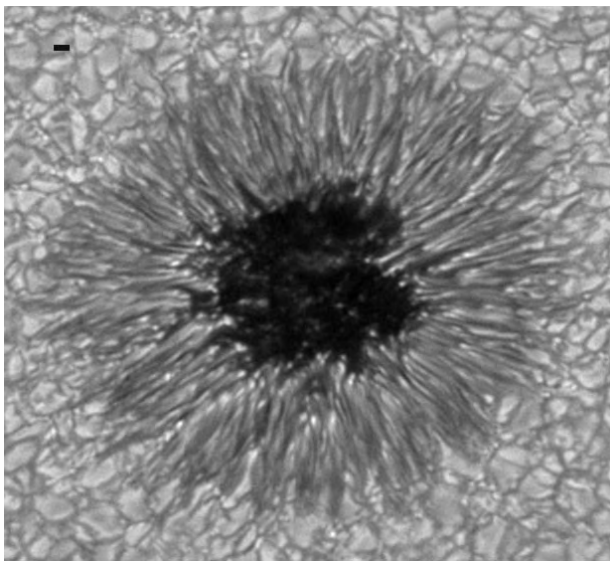

Figure 2. Mature sunspot observed at the Swedish Vacuum Solar Telescope at the Observatorio del Roque de los Muchachos (La Palma). The black strip on the upper left corner of the image is $1'' \approx 725$ km long. This image, and that in figure 3, have been corrected for the degradation produced by the telescope and the average atmospheric conditions at the observing site.

Umbral cores

Umbral cores have smoothly varying intensities with brighter and darker regions, known as the diffuse background (DB), which has two principal features, the dark nuclei (DN), which correspond to distinctive local intensity minima of the core, and umbral dots (UDs), small bright structures embedded in the diffuse background. A mature sunspot with an umbra displaying all these fine structures is shown in figure 2.

Dark nuclei

They are the zones around the minima of local brightness inside the umbra. The name 'void' has also been used. The brightnesses are spread in a wide range (see table 1) depending of the individual characteristics of umbral cores (e.g. size). Since the continuum brightness is related to the magnetic field strength, DN are also the locations of the strongest magnetic fields. The DN are not necessarily located at the center of the umbra, but are rather distributed irregularly in the umbral cores and are almost free of bright structures.

The intensity minimum of the umbral core is the parameter that best characterizes the thermodynamic properties of an umbral core. It is correlated with the sunspot size; this means that larger sunspots are darker.

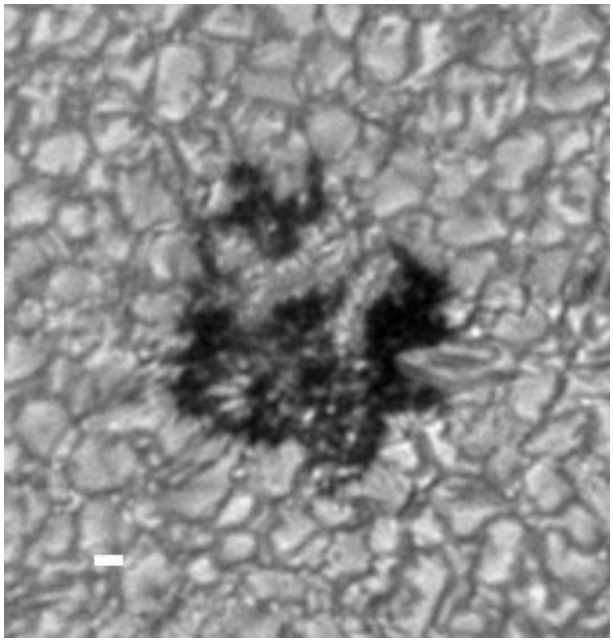

Figure 3. Solar pore observed at the Swedish Vacuum Solar Telescope at the Observatorio del Roque de los Muchachos. Two faint light bridges are observed at the upper part and a lot of umbral dots are embedded in the diffuse background. The white strip on the lower left corner corresponds to $1'' \approx 725$ km.

Umbral dots

Due their morphological similarity to photospheric granules, the bright structures in the umbra were first named 'umbral granulation'. Stratoscope observations showed that they were much narrower and darker than granulation (see SOLAR PHOTOSPHERE: GRANULATION) and they have accordingly received the name 'umbral dots'. However, like photospheric granules, UDs do not have a typical size or lifetime, the smallest (0.2″) and shortest-lived (3 min) ones being the most numerous.

The brightness of UDs in sunspots is related to the brightness of the surrounding diffuse background. On average, we have

$$I_{\rm ud} \approx 3 \times I_{\rm db}$$

where $I_{\rm ud}$ and $I_{\rm db}$ are the intensities of the umbral dots and the diffuse background respectively.

The brightest and fastest moving UDs (0.5 km s^{-1}) are found far from the DN. The fraction of umbral surface occupied by UDs, the so-called filling factor, does not exceed 10 per cent.

UDs in pores (see figure 3) are similar to those in mature umbras but are longer-lived and brighter, and have a higher filling factor.

During their lifetime, UDs show variations in brightness. Significant peaks at periods between 3 and 34 min have been detected.

At least some UDs are connected with other structures outside the umbra. This has been demonstrated by using time series of images of mature sunspots, such as that in figure 2. These show bright elements in the penumbra (penumbral grains) moving into the umbra. A few cross the penumbra/umbra boundary, becoming UDs, which move further into the umbra. When they meet a DN, they brake their motion and disappear. It has been observed that the encounter of a UD with a DN produces a brightening of the UDs located on the opposite side of the nucleus. If these brightenings are produced by a perturbation propagating across the DN, the velocities of propagation would range between 2 and 7 km s^{-1}.

A complementary view of the dynamics of UDs has been provided by time-series observations of solar pores. The existence of a direct interface between the photosphere and the umbra has allowed the possible relation between granules and UDs to be studied. Small granules located close to the pore are pushed by the mesogranular flows and sometimes penetrate into the pore. From there they move inward as features similar to UDs.

Light bridges

Umbral cores are crossed by bright structures that in some cases completely split the umbra into two separate umbral cores. Such features were named bridges because they were originally interpreted as structures overlying the umbra and were thought to consist of facular material. Nowadays we know that they are an intrinsic part of the sunspot and represent the first clear manifestation of sunspot decay. The oscillations (see SUNSPOT OSCILLATIONS AND SEISMOLOGY) observed in LBs are not in phase with those of the adjacent UCs; this supports the idea that, although both are at the same level in the atmosphere, they are physically different structures.

LBs are classified, according to their width, as:

(a) *Faint light bridges* (FLBs; also known as 'umbral bridges'): These are narrow bright streamers, which do not split the umbra. Their brightness is similar to, or lower than, that of the penumbra. FLBs show granule-like structures, $\approx 0.5''$ wide, similar by size to UDs and small granules observed in fields of abnormal granulation.

(b) *Strong light bridges* (SLBs; also known as 'photospheric bridges'): Broad structures ($>2''$) which cross the umbra, dividing it into two or more UCs. Their brightness is related to their width, and reaches photospheric values for the broadest ones.
SLBs show two different populations of granules. One family consists of structures of sizes similar to those of FLBs, and the other with granules similar in size to photospheric granules. The second family begins to dominate with increasing width.

In complex δ sunspots, bridges with filamentary structure, joining umbral cores of different magnetic polarity, are observed. For this reason they are called 'penumbral bridges'. They represent a different physical process and will not be considered further here.

A unified view of umbral fine structure

Table 1 summarizes the main observed properties of sunspot fine structure.

Table 1. Characteristics of the main fine structures observed in sunspots (excluding pores). For LBs the size and brightness correspond to the individual grains, and the lifetime to the whole structure. The brightnesses are wavelength dependent and here are indicated as a fraction of the mean photospheric intensity in the green spectral range.

Structure	Size (″)	Brightness	Lifetime
SLB	1.2	0.6–1.0	Days
FLB	0.5	0.5–0.7	
DN	1.5	0.1–0.4	Days
UD	<0.60	0.2–1.0	Minutes

All these different acronyms, structures and properties are probably just a manifestation of the same physical process seen at different levels. In the framework of the cluster model of sunspots (see SUNSPOT MODELS) this process could be the penetration of field-free material from below the solar surface into the sunspot photosphere as a consequence of the weakening of the sunspot magnetic field.

We can present the following picture of the formation and decay of a sunspot:

The magnetic flux emerging from the bottom of the convection zone appears in the photosphere in a fragmented form. A sunspot is formed by the coalescence of different bundles of magnetic flux or sunspot fragments, which are held together by magnetic buoyancy.

Some physical parameters associated with the emergence, such as the twisting of the bundles or the amount of emergent magnetic flux, determine the internal magnetic and thermal structure of the sunspot in the subphotospheric layers, where the fragments preserve their individuality.

In places where the fragments cannot be held together, the subphotospheric material will start to penetrate the photosphere giving rise to the observed bright structures in the sunspot umbra. The brightness, size and motion of these structures will depend on the strength and inclination of the magnetic field in the surrounding areas.

We can assume the existence of two different types of UDs: (a) dark and slow-moving UDs located in and between dark nuclei, which are produced by intrinsic instabilities of the umbra and (b) bright and fast-moving UDs embedded in a relatively bright DB in the peripheral parts of the the umbra, and possibly originating from the penetration of penumbral grains and/or small photospheric granules.

Some UDs are aligned to form FLBs in the interstices of the sunspot fragments. Later, some of these FLBs become wider and brighter, converting to SLBs and producing the splitting of a UC. In these areas the re-establishment of normal photospheric conditions starts, which means the presence of granulation. Sunspots with a larger area occupied by bright fine structures suffer a more rapid decay. The erosion of the sunspot boundaries by the adjacent granules and the splitting of umbral cores by LBs is the observational fingerprint of the sunspot decay, combined with the outward flow of the moving magnetic features.

All these phases should be controlled by the mechanisms that hold together the different components of a sunspot in subphotospheric layers. In the near future, improvement in the techniques of local helioseismology (see SOLAR INTERIOR: LOCAL HELIOSEISMOLOGY) could reveal the sub-photospheric component, i.e. the roots, of the observed fine structures in the sunspot umbra. So far, downflows have been observed in these layers, which could make possible the cohesion of the sunpots fragments.

Most of these evolutionary links between umbral fine structures remain to be observed throughout the full evolution of a single sunspot and we probably need to wait for the operation of a large solar telescope in space.

From the proposed scheme we can expect a reduction in magnetic field and the presence of upward motions in the bright structures. In fact, magnetic field reduced by 20–40% relative to the surrounding umbra has been observed in SLBs, also showing more inclined field lines giving rise to a canopy-like structure. A reduction of 1–20% has also been observed in regions rich in UDs, but without any fluctuations corresponding to individual UDs. This can be explained by taking into account the fact that the continuum (where the UDs are observed) is formed deeper in the photosphere than the spectral lines, where the velocity and magnetic fields are measured.

Instead of penetrative convection in a cluster model of sunspots, we can also assume that the underlying physical process consists of convection in the presence of a coherent magnetic field (see MAGNETOHYDRODYNAMICS: MAGNETOCONVECTION). In this case, the theoretical prediction is also coherent with the observational view of umbral bright features presented here, and we cannot decide at present which of these two mechanisms, penetrative convection or magnetoconvection, is the right one.

Sunspots

Sunspots are the sites of strong magnetic fields at the surface of the Sun. They are visible as features that appear dark because they are cooler than the surrounding SOLAR PHOTOSPHERE, owing to partial suppression of convective energy transport by the magnetic field. Sunspots are distinguished from SUNSPOT PORES by having a filamentary SUNSPOT PENUMBRA surrounding a dark SUNSPOT UMBRA. Their diameters range from 3600 km to 50 000 km and a typical spot survives for less than a week, though some large spots persist for several months. Spots are the most prominent signs of solar magnetic activity, and they have been observed systematically since telescopes were invented in the seventeenth century. They occur in bands centered on the equator that extend to latitudes of $\pm 30^\circ$ and their distribution varies with the SOLAR CYCLE, which has an average period of about 11 years. Although sunspots cover less than 0.1% of the solar surface there are other stars that are similar to the Sun but much more active, possessing starspots that cover more than half their surfaces (see SOLAR–STELLAR CONNECTION).

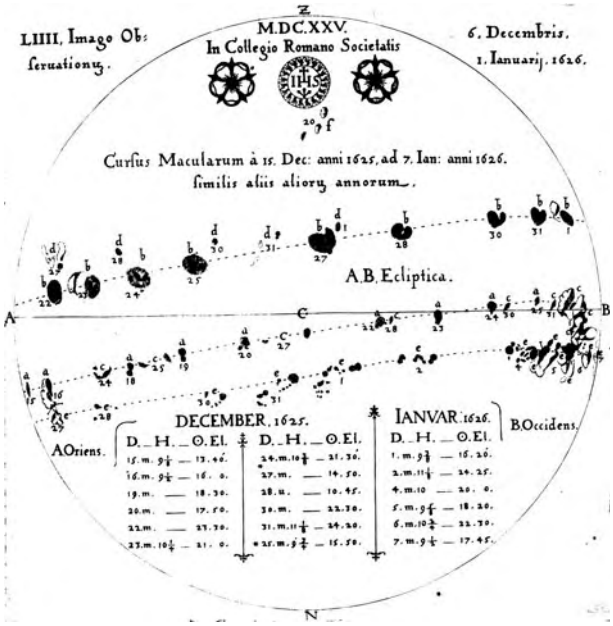

Figure 1. Diagram showing spots moving across the disk of the Sun as it rotates, from Scheiner's *Rosa Ursina sive Sol*, 1628. (Courtesy of the Royal Astronomical Society.)

Historical introduction

Though there are early Chinese records of sunspots their modern history begins in 1611. In that year Johann Fabricius, Christoph Scheiner, Galileo Galilei and Johann Kepler all turned their telescopes to the Sun and found sunspots. Moreover, Galileo interpreted their motion across the visible disk as evidence that the Sun was itself rotating with an apparent period of about 27 days (see figure 1). He also realized that although they were dark relative to their surroundings they were nevertheless as bright as the brightest regions of the Moon. The spots excited considerable interest, which persisted throughout the century. Many observers noticed that sunspots were less frequent between 1645 and 1715, and the record of routine observations at the Paris Observatory confirms that this episode of reduced activity (the Maunder Minimum) was indeed a real effect.

Interest lapsed in the eighteenth century. The early observers had already distinguished the dark central umbra from the annular penumbra but it was not until 1769 that Alexander Wilson noticed that spots appeared increasingly foreshortened as they rotated towards the limb of the Sun. He correctly interpreted this as showing that the visible surface of a spot is depressed relative to the surrounding photosphere (see SUNSPOTS: WILSON EFFECT). Further progress came when William Herschel constructed his 10 ft telescope and used it to observe sunspots in much greater detail: he asserted that they were openings in the solar surface which revealed a cooler layer that might be habitable. Heinrich Schwabe, after observing assiduously for 17 years, announced in 1843 that the incidence of sunspots varied cyclically with a period of about 11 years; this pattern was confirmed by Richard Carrington, who also noted that the spots first appeared at latitudes of around $\pm 30^\circ$ and then filled zones that expanded towards the equator, before contracting and then disappearing at sunspot minimum, as spots of the next cycle appeared at higher latitudes. He also established that the Sun did not rotate uniformly and that the rotation period was shortest for spots in the vicinity of the equator (see SOLAR INTERIOR: ROTATION).

The development of spectroscopy transformed the study of the Sun. Joseph Fraunhofer had discovered absorption lines in the solar spectrum in 1814 and Gustav Kirchhoff realized that they revealed the composition of the solar atmosphere; by 1860 Norman Lockyer and Angelo Secchi were comparing spectra of sunspots with those from the surrounding photosphere. At the turn of the century George Ellery Hale developed the spectroheliograph to produce images of the solar surface in a single spectral line and in 1908 he exploited the ZEEMAN EFFECT (splitting of a spectral line in a magnetic field) to measure the magnetic field in sunspots. The Doppler shift associated with radial outflows in the penumbra (see SUNSPOTS: EVERSHED EFFECT) was detected about a year later. Since then, observations have been dominated by the drive to obtain more detailed spectroscopic results and higher spatial resolution—from the ground, from balloons, and increasingly from space.

These results have stimulated theoretical developments. Ludwig Biermann first suggested that sunspots were cool because convection, which supplies energy to the normal photosphere, was inhibited by their strong magnetic fields. The subsequent formulation of MAGNETOHYDRODYNAMICS by Hannes Alfvén and Thomas Cowling led to a description of this interaction which has been ex-

Dirac House, Temple Back, Bristol, BS1 6BE, UK

tended through numerical modelling of nonlinear magnetoconvection (see MAGNETOHYDRODYNAMICS: MAGNETOCONVECTION). In parallel with this, the work of Eugene Parker and others has led to an understanding of hydromagnetic DYNAMO THEORY as an explanation for global features of the sunspot cycle.

Sunspot groups and active regions

Sunspots typically appear in groups like that shown in figure 2. Frequently there is a dominant pair of spots, oriented roughly parallel to the solar equator, which start close together and move apart as the group evolves, achieving separations of up to 20°. Normally the preceding spot (in the sense of the Sun's rotation) is much more prominent than the follower and has a longer lifetime (see SUNSPOT EVOLUTION). Spot groups lie within SOLAR ACTIVE REGIONS, containing pores and smaller magnetic features that give rise to bright faculae and fine-scale filigree in the solar photosphere (see SOLAR PHOTOSPHERE: FACULAE; FILIGREE). There is a continuous family of isolated magnetic features that can be parametrized by the magnetic flux that they contain. The smallest flux elements have fluxes of 0.001 TWb (10^{17} Mx) and diameters of about 100 km, with fields of up to 0.15 T (or 1.5 kG)—sufficient to balance the external gas pressure, so that the flux tubes are almost completely evacuated at the photosphere (see SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES). These flux elements nestle between the convection cells that give rise to the photospheric GRANULATION. Pores are larger: they are isolated umbras, both darker and cooler than the normal photosphere, with fields of around 2000 G and fluxes of up to 7 TWb. Larger flux concentrations invariably develop the filamentary penumbra that surrounds the umbra and distinguishes sunspots from pores. The lifetimes of sunspot groups range from a few days to several months. Although most sunspots survive for less than a week there are examples of large individual spots that survive for much longer and return several times as the Sun rotates.

The polarities of the magnetic fields in sunspots follow Hale's law. Within any group or active region the preceding and following spots have oppositely directed fields and most of the magnetic flux that emerges from one side of the region returns back through the other. At any stage of the solar cycle the preceding and following spots have opposite polarities in the northern and southern hemispheres. Thus there is a strong azimuthal (or toroidal) field emerging through the photosphere which is antisymmetric about the equator (see SOLAR MAGNETIC FIELD). The sense of these fields reverses at the end of each 11 year activity cycle, so that the full magnetic cycle has a period of 22 years.

The structure of individual sunspots

Photospheric structure

The diameters of sunspots can extend, as in one famous case, up to 130 000 km—approximately one-tenth of the solar diameter or ten times the diameter of the Earth. A typical well-developed sunspot, like that in figure 2, is roughly circular and has a diameter of 20 000–30 000 km. Spots have structures that scale with the radius R, depending only on the ratio r/R, where r is the distance from the center of the spot. The central dark umbra has a radius $0.4R$ and a temperature of about 4300 K, 2100 K below that of the surrounding photosphere; as a result it radiates at only 24% of the normal photospheric rate. Surprisingly, the umbral intensity varies with the solar cycle: in the infrared it increases by 20% from sunspot minimum to sunspot maximum. Within the umbra there are small bright features (umbral dots) with diameters in the range from 1800 km to the limit that can be resolved and with a typical value of about 250 km. Their temperatures are comparable with that of the undisturbed photosphere and the larger ones have lifetimes of 30–60 min.

The umbra is surrounded by a filamentary penumbra, occupying 85% of the total area and with an average intensity that is 75% of the photospheric value. Figure 2 shows the irregular filamentary striations, with local intensity ratios varying from 60% in the dark filaments to 95% in bright filaments. The latter are made up of aligned bright grains that migrate towards the umbra with velocities of up to 0.5 km s^{-1}, while the dark filaments include clouds that move out towards the edge of the penumbra. Spectral lines from matter within the dark filaments show Doppler shifts that correspond to outflows with velocities that rise to a maximum of 6 km s^{-1} at the edge of the spot (the Evershed effect).

The magnetic field at the center of a sunspot is nearly vertical, with a magnitude of up to 0.3 T (see SUNSPOT MAGNETIC FIELDS). As r increases the azimuthally averaged field becomes increasingly inclined, reaching an angle of 70° at the outer edge of the penumbra, while its strength decreases to around 0.1 T before dropping abruptly to zero within a distance too small to be resolved. The fine structure of the penumbral field is amazingly complex, for the field directions in the bright and dark filaments differ by 30–35°, with the dark filaments more nearly horizontal. Near the umbra, where the mean field is inclined at an angle of 45° to the vertical, the bright filaments have an inclination of only 30°, while the dark filaments are almost horizontal (and parallel to the Evershed flow) at the outer boundary. There is as yet no adequate explanation for this interlocking comb-like structure.

The atmosphere above sunspots

Observations made in the Hα line of the hydrogen Balmer series ($\lambda = 6562$ Å) show a rich pattern of radial fibrils extending outwards from a sunspot to form the 'superpenumbra'. This pattern starts at the edge of the umbra and fills an annular region with radius about $2R$. The fibrils exhibit time-dependent behavior with ringlike features propagating radially outwards, referred to as running penumbral waves (see SUNSPOT PENUMBRA: STRUCTURE AND ACTIVITY). The Hα line is formed in the CHROMOSPHERE at heights around 3000 km above the solar surface and the fibrils represent the intersections of slender magnetic flux loops with this region of the chromosphere.

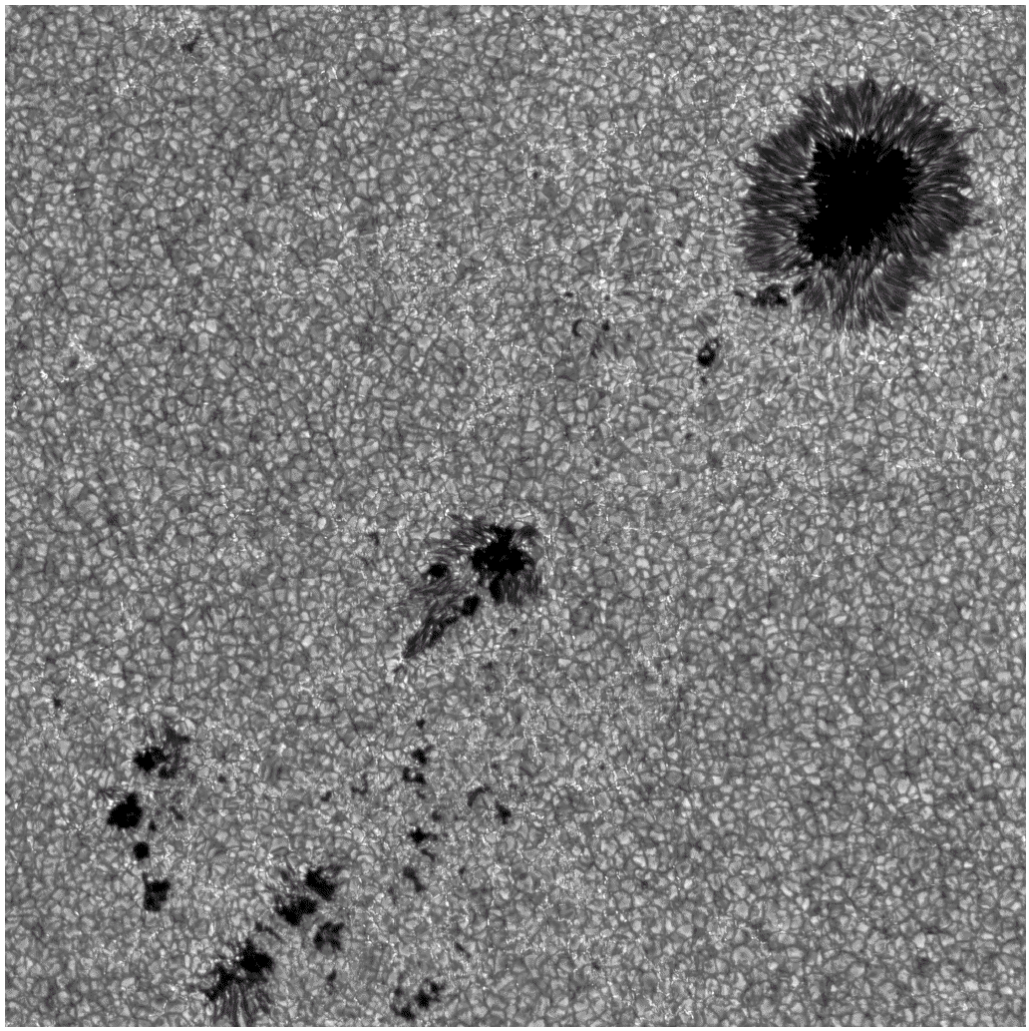

Figure 2. A sunspot group, showing a large preceding spot accompanied by a smaller companion, at top right, and a cluster of small spots and pores with opposite polarity at bottom left. This image, taken in the CH G-band by T Berger and G Scharmer at the Swedish Vacuum Solar Telescope on La Palma, covers a region 120 000 km square on the surface of the Sun with north towards the top left corner. The solar granulation is clearly visible and the small bright points in the intergranular lanes are the sites of locally intense magnetic fields. For an enlarged image of the big sunspot see SUNSPOT PENUMBRA. (Courtesy of T Berger, Lockheed–Martin Solar and Astrophysics Laboratory, Palo Alto.)

These loops have one footpoint within the spot and may return at a great distance from it. Many of them extend up into the hot CORONA and are visible as CORONAL LOOPS in the extreme ultraviolet and in soft x-rays.

The atmosphere above a sunspot supports two different types of oscillations (see SUNSPOT OSCILLATIONS AND SEISMOLOGY). Those with periods around 3 min are resonant oscillations of the magnetized umbral atmosphere itself, while the 5 min oscillations are driven by p-mode oscillations in the convection zone around the spot. The latter provide a means of exploiting HELIOSEISMOLOGY to probe the structure of the spot below the photosphere.

Subphotospheric structure

Continuum observations reveal a surface of constant optical depth. In the umbra of a sunspot this surface lies about 500 km below its level in the ambient photosphere. This Wilson depression implies that the gas pressure in the umbra is much less than that outside the spot at the same geometric level, and therefore that magnetic stresses are required in order to maintain hydrostatic equilibrium in any SUNSPOT MODEL. Since magnetic flux is conserved, the fields that emerge through the surface of a sunspot must continue below the photosphere; the systematic behavior of sunspot groups indicates that the resulting flux tube extends deep into the convection zone (see SOLAR INTERIOR: CONVECTION ZONE) and local helioseismology (see SOLAR INTERIOR: LOCAL HELIOSEISMOLOGY) confirms that there

is a coherent flux tube for at least 10 000 km below the surface. Within this flux tube energy is carried upwards by convection, though radiation takes over just below the umbral photosphere (see SOLAR INTERIOR: CONVECTION THEORY). Thus the flux tube can be regarded either as an inhomogeneous plug or as a tight cluster of isolated flux tubes, separated by weaker fields or even (in the limit) by field-free plasma. Either picture is compatible with the observations.

Outside the sunspot, energy is transported by convection and several different horizontal scales, corresponding to granulation, mesogranulation and supergranulation, are visible at the photosphere (see SOLAR PHOTOSPHERE: GRANULATION; MESOGRANULATION; SUPERGRANULATION). A well-developed sunspot is surrounded by an annular moat cell—essentially an abnormally large and long-lived supergranule, stabilized by the flux tube at its core—whose diameter may be twice that of the spot. Within the moat there is a vigorous radial outflow which sweeps magnetic fields to its periphery, leaving the moat free of magnetic fields apart from small features (with both polarities) that migrate outwards as the spot decays (see SUNSPOTS: MOVING MAGNETIC FEATURES AND MOAT FLOW). The field inclination at the photosphere indicates that the flux tube contracts below the sunspot. Models imply that the radius of the underlying flux tube is less than $0.5R$, so the energy radiated from the penumbra can be drawn predominantly from the plasma below the magnetopause (the sharp boundary of the flux tube). Such curved boundaries are liable to interchange instabilities but here the magnetopause is strongly inclined and is stabilized by MAGNETIC BUOYANCY. It is nevertheless clear that the observed dynamical stability of sunspots requires the presence of a collar around the flux tube at some greater depth. Recent observational and theoretical results suggest that there may be a slender counterflow beneath the penumbra and within the moat cell. The resulting inflow could act as a collar and so preserve the spot.

Magnetoconvection

Sunspots provided the original motivation for studying the effects of magnetic fields on convection in conducting fluids. The simplest models assume the presence of an imposed vertical field (as in the umbra), which always reduces the efficiency of convection. If the field is strong enough, convection is completely suppressed but as the field strength is reduced, convection sets in, either as oscillations or as steady overturning motion. It is easily shown that radiative transport is not able to supply even the reduced energy flux emerging from the umbra, so convection must take over just below the visible surface. Numerical experiments on nonlinear magnetoconvection suggest that the umbral dots are just chaotic plumes of hot rising gas that penetrate into the photosphere.

As the field becomes more inclined the pattern of convection changes, and rolls with their axes parallel to the horizontal component of the field are preferred. In simple pore models the inclination increases with increasing flux until it reaches a critical value that favors the development of radial filaments and leads to the abrupt formation of a penumbra. This new form of time-dependent filamentary convection is apparently able to transport energy through the penumbra from the magnetopause.

Systematic properties of sunspots

The solar cycle

The butterfly diagram in figure 3 shows the incidence of sunspots as a function of latitude and time. Although individual sunspots and active regions are irregularly distributed, their average behavior is quite systematic (see SUNSPOT CLASSIFICATION). The number of spots is conventionally measured by the sunspot number, an arbitrary measure of activity that is well correlated with sunspot areas (shown in figure 3), as well as with, for example, SOLAR FLARES or coronal x-ray and radio emission (see SOLAR ACTIVITY INDICES). Since 1700 the sunspot number has varied cyclically, with a well-defined mean period of 11.1 years. The solar cycle varies irregularly in amplitude but the available timeseries is not long enough to establish whether this variation is deterministic (chaotic) or stochastic.

Since sunspots are caused by magnetic fields erupting from the interior of the Sun and those fields obey Hale's law, the underlying magnetic cycle has a mean period of 22 years. Magnetic activity is a common feature of stars with deep outer convection zones and cyclic activity is found in middle-aged, slow rotators like the Sun. The scale and systematic properties of active regions suggest that they are formed near the base of the convection zone or even in a region of weak convective overshoot and it is generally accepted that these oscillating fields are maintained by a hydromagnetic dynamo.

The solar dynamo is probably located near the interface between the convection zone and the underlying radiative zone, where there are steep radial gradients in angular velocity (see SOLAR INTERIOR). As strong toroidal fields, with strengths as high as 10 T, are built up they eventually become liable to MAGNETOHYDRODYNAMIC INSTABILITIES driven by magnetic buoyancy. These instabilities could grow until they eventually liberate isolated $\cap$-shaped loops of toroidal flux. The loops would float upwards through the convection zone, developing a Ω-shape as they expand, and then break through the surface to form active regions and sunspots (see SOLAR INTERIOR: EMERGING MAGNETIC FLUX TUBES).

Origin of cyclic magnetic activity

Dynamo theory provides a mechanism for cyclic reversals of the toroidal magnetic field, on a timescale very much shorter than that for decay through ohmic resistivity in the Sun (which is comparable to its lifetime on the main sequence). This mechanism relies on two physical processes. The first is straightforward: a meridional (or poloidal) field in a differentially rotating star will be drawn out to give a strong toroidal component. The second process invokes cyclonic eddies to generate a

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

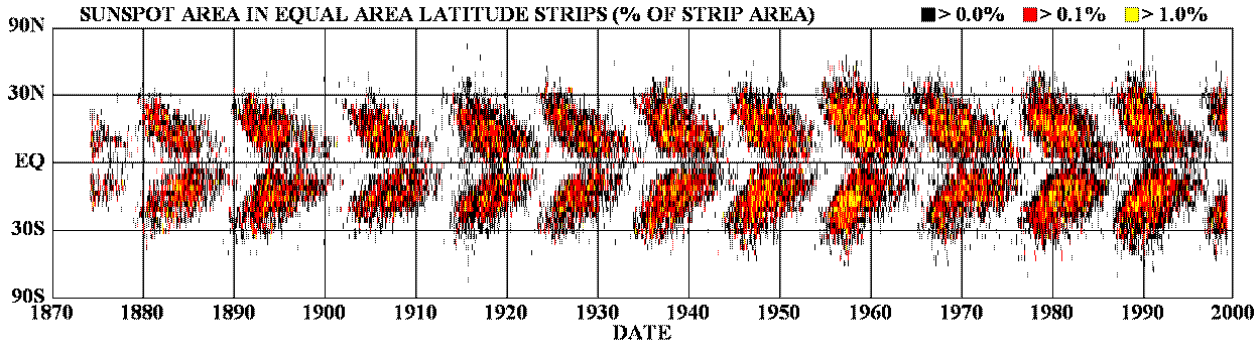

Figure 3. Butterfly diagram showing the observed distribution of sunspots in latitude and time since 1875. At the beginning of the activity cycle spots appear around latitudes of $\pm 30^\circ$ and by sunspot maximum activity extends to the equator. The zones of activity then dwindle until, at sunspot minimum, the last spots of the old cycle appear at low latitudes as the new cycle starts. The distribution of spots is very nearly symmetrical about the equator. (Courtesy of D H Hathaway, NASA/MSFC.)

reversed poloidal field by distorting the toroidal field; these are convective plumes with a mean HELICITY imparted by the Coriolis force. The cycle can then proceed. Most calculations have relied on a simplified form of the theory (mean field electrodynamics), which captures the essence of these processes and yields solutions that reproduce the essential features of the solar cycle (see DYNAMOS: SOLAR AND STELLAR).

The key parameter in stellar dynamo models is the angular velocity Ω, which controls both differential rotation and helicity. If Ω is small, the field-free state is stable to magnetic perturbations. Dynamo action is only possible if Ω exceeds a critical value at which cyclic activity appears as a magnetic instability. As Ω is increased the oscillations grow in amplitude, and more complicated patterns of activity may appear. In fact this sequence follows the evolution of a star like the Sun in reverse, since it arrives on the main sequence spinning rapidly and magnetically very active, and is then spun down by magnetic braking (see SUN AS A STAR and SOLAR EVOLUTION).

Modulation of cyclic activity

The earliest sunspot observations show that the cycle operated then as now but spots became less frequent after 1645 until in the last decade of that century only one spot was observed. Moreover, there were relatively few spots in the cycle that reached its maximum in 1706 and almost all of those were in one hemisphere (unlike the butterflies in figure 3). There were many observers active during this period and there is no doubt that this episode of reduced activity—the Maunder Minimum—was real. Fortunately it is possible to extend the sunspot record back by using proxy data: isotopes such as ^{14}C and ^{10}Be (which are preserved in trees and polar ice, respectively) are formed as a result of galactic cosmic rays impinging on the atmosphere. Since the cosmic ray protons are deflected by magnetic fields in the solar wind, the abundances of cosmogenic isotopes are anticorrelated with solar activity. The ^{14}C and ^{10}Be records show not only the Maunder Minimum but also many previous grand minima recurring aperiodically every few hundred years for the past 10 000 years (see SOLAR ACTIVITY: LONG-TERM RECORDS).

Nonlinear dynamo models are able to reproduce this pattern of aperiodic modulation. As Ω is increased, the periodic cycles may themselves become unstable to oscillations with a much longer period. This transition leads to periodically modulated cycles. As Ω is further increased, the amplitude of the modulation grows until there is a further transition to behavior that is chaotic. Symmetry about the equator may also be broken, especially as solutions are emerging from grand minima.

Sunspots and climatic change

Ever since sunspots were discovered there have been speculations as to their effect on climate. Satellite observations show that the solar luminosity varies with the sunspot cycle and is greater by about 0.15% at sunspot maximum. The estimated increase in SOLAR IRRADIANCE since the Maunder Minimum has a similar value, which might cause an increase of around 0.3 K in global temperature. Comparisons between the sunspot and climatic records suggest that temperature fluctuations are indeed significantly correlated both with the 11 year cycle and with its long-term modulation. The extent to which solar activity has contributed to climatic change is controversial (see SOLAR–TERRESTRIAL CONNECTION: LONG-TERM AND SHORT-TERM CLIMATE VARIABILITY). It seems likely that this has, until recently, been a major effect but that global warming is now predominantly due to greenhouse gases released by burning fossil fuels.

Sunspots: Evershed Effect

The Evershed Effect is an observational effect in the penumbra of SUNSPOTS consisting in displacements of the spectral line profiles towards either shorter wavelengths (that is, blueshifts) in the zones closest to the Sun's disk center or larger wavelengths (that is, redshifts) in those zones closest to the solar limb. Since the first detection in 1909, this effect was correctly interpreted by its discoverer Evershed (1909) as the consequence of mostly horizontal movements of material emanating radially from the spot. Soon after the discovery, a strong variation of the effect with height was detected: the flow was directed inwards when observed in spectral lines formed in the high layers of the sunspot's CHROMOSPHERE (the so-called inverse Evershed effect; see Maltby (1997) for a review). From then on, the Evershed effect has been one of the most prominent dynamical phenomena we see on the Sun and is in fact superimposed on several others (most certainly caused by different physical mechanisms) that take place in the penumbra (see SUNSPOT OSCILLATIONS AND SEISMOLOGY and SUNSPOT PENUMBRA: STRUCTURE AND ACTIVITY). Hence, disentangling the physical process which gives rise to the Evershed effect is one of the most exciting challenges facing solar physics. A very good account of current knowledge and problems, as well as relevant references on this topic, can be found in the two recent reviews by Thomas (1994) and by Maltby (1997).

Main observational features

Early in this century, the widespread belief was that sunspots were made up of strong cyclones or whirls. This was indeed what prompted G E Hale to look for magnetic fields in them (see SUNSPOT MAGNETIC FIELDS) under the assumption of the presence of free, electrically charged particles rotating around the spot axis (the magnetic field would emerge in very much the same way as in today's electromagnets). With the aim of detecting such gyrating motions, Evershed undertook the observation of several FRAUNHOFER LINES in different spots as they crossed the solar surface as a result of solar rotation.

All the basic observational features were established already as early as this pioneering work.

(i) All the spots show line displacements of the same order of magnitude, at the same distance from the disk center, no matter the solar hemisphere they are in.
(ii) The larger the heliocentric angle (angular distance from the disk center) the larger the shifts, which eventually disappear when the spot is located very close to the disk center.
(iii) Blueshifts always occur in the penumbral half closest to the disk center and redshifts in the half closest to the solar limb. No shifts are present at 90° from the direction of the disk center.
(iv) The largest shifts take place in the outermost parts of the penumbra and seem to cease abruptly at the visible penumbral border.

From these observational facts he concluded that the material motions must essentially be horizontal (parallel to the solar surface) as witnessed by the center-to-limb variation (see SOLAR PHOTOSPHERE: CENTER-TO-LIMB VARIATION) of the line displacements which only give information about the component of the vector velocity along the line of sight. Any vortex motion had to be discarded in view of feature 3.

In 1913, C E St John (see reference in, for example Maltby (1997)) reported the observation of 506 lines which confirmed Evershed's results, and he complemented them by finding a proportionality between wavelengths and displacements, clearly obeying the DOPPLER EFFECT due to material motions. Moreover, he found that stronger lines (assumed to be formed higher in the atmosphere) show the opposite effect; that is, material motions towards the central parts of sunspot umbrae. Hence, outward motions were confined to the photosphere while inward motions were located in the chromosphere, with a probably neutral velocity layer in between.

Since those early days, the observational picture of the Evershed effect remains virtually unchanged, while, naturally, more evidence has been compiled and better details obtained because of the increasing degree of sophistication in instrumentation and spectral resolution. Thus, the effect is known to be time dependent and likely to be concentrated in the dark penumbral filaments. Line-of-sight velocities of up to 6 or 7 km s^{-1} (and typical values around 3–4 km s^{-1}) have been observed and it is currently known that absorption lines in the penumbra show asymmetric profiles (i.e. that the line wings are more shifted than the line cores). Such asymmetries have been interpreted as a consequence of a gradient with height of the line-of-sight component of the material velocity and of the vector magnetic field, hence confirming St John's and Evershed's results in a modern way. In figure 1 we see the typical shape of the four Stokes parameter profiles I, Q, U and V (see SOLAR MAGNETIC FIELD: INFERENCE BY POLARIMETRY) observed in a sample point of the limb-side penumbra. The spectral region shows two neutral iron lines located at 630.15 nm and 630.25 nm (in a laboratory wavelength scale denoted by dotted lines), plus two telluric lines from atomic oxygen (the thinner ones in the I plot, formed in the Earth's atmosphere and, hence, with no polarization signal in the Q, U and V plots). The Stokes parameters are normalized to the local quiet sun continuum intensity. Note the redshift and the strong asymmetry displayed by the solar profiles. (The shapes of the asymmetric Q and U profiles conspire, in this particular case, to hide apparently the shift in wavelength.)

The essentially horizontal character of the material motions is in fairly good agreement with the increasingly horizontal magnetic field lines present in penumbrae as one moves away from the sunspot center, since the magnetic field should be frozen to the solar plasma, i.e. the gas should follow the magnetic field lines (see MAGNETOHYDRODYNAMICS). Perhaps the most intriguing phenomenon is the claimed sharp disappearance of any

Doppler signature outside the outer visible boundary of the penumbra: just inside this boundary, that is, in the outermost penumbra, it is where the line-of-sight velocities are largest (feature 4 above). If the Evershed effect is indeed the signature of a material flow, where does the mass flux go?

More observational evidence and a reconciling picture

Some authors still assert that the Doppler signatures of the effect cannot be tracked down farther than 1 arcsec away from the penumbral limits. However, reports on tracing the Evershed effect beyond the outer penumbral rim started to appear in the scientific literature by the mid-1980s (Thomas 1994) and continue until today. Particularly interesting is the detection by Rimmele in 1995 (see Maltby (1997) for the reference) of Evershed motions taking place along narrow, elevated channels in the penumbra, some extending far beyond the outer penumbral rim. Through such channels, the material seems to be carried from an upstreaming footpoint, always located within the penumbra, towards a downstreaming footpoint more distant from the sunspot center. This detection was possible after careful examination of observations performed in two lines with fairly different sensitivity to the velocities at different atmospheric layers. The debate about whether or not the Evershed signatures continue away from the spot is certainly not caused by different spatial resolutions since observations with very high resolution (about 350 km on the Sun) have been interpreted according to each possibility (see, e.g. Thomas (1994) for references). The discrepancy must stem from the different sensitivity to the sunspot atmospheric quantities (not only the line-of-sight velocity) of the observing and analysis techniques used by the various researchers.

Further evidence of Evershed flows following the magnetic field lines has been obtained by Solanki, Montavon and Livingston in 1994 (see the reference in Thomas (1994)) with the detection of line-of-sight velocities of up to 2 km s^{-1} in the magnetic 'canopy' which extends beyond the visible penumbral boundary and above the solar surface as seen in the white-light continuum. This detection offered an interesting solution to the aforementioned missing-mass problem, since those velocities could only be inferred from observations with spectral lines sensitive to the elevated layers of the canopy, remaining undetectable from observations of normal photospheric lines: the material could be carried away from the spot through the magnetic canopy. However, the exponential decrease of DENSITY with height in the solar atmosphere (see SOLAR ATMOSPHERE: EMPIRICAL MODELS and SOLAR PHOTOSPHERE) implies that this canopy solution is unlikely because only much higher velocities than the quoted value of 2 km s^{-1} could account for the total mass flux carried within the limits of the penumbra (the mass flux is essentially an integral of the product between density and velocity).

A reconciling observational picture was recently

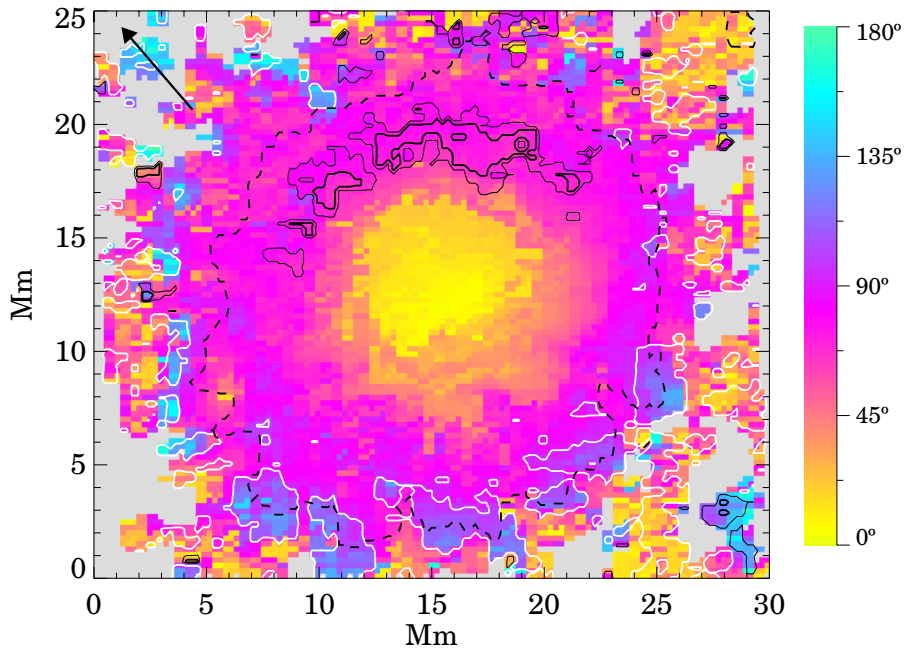

Figure 2. Map of the magnetic field inclination of a sunspot as measured from the vertical to the solar surface. The observations were obtained with the ASP in June 1992 and correspond to a spot located some 16° away from the disk center. Superimposed are contours of the largest line-of-sight velocities retrieved at the lowest optical layer observable (continuum optical depth unity): blueshifts are in dark lines (thick, -3 km s^{-1}; thin, -1.5 km s^{-1}), redshifts are in white lines (3 km s^{-1}). The arrow points to the solar disk center. The outer visible boundary of the penumbra is indicated with a dashed line. Adapted from *Nature* (Westendorp Plaza *et al* 1997).

obtained by Westendorp Plaza *et al* (1997) who, by using a novel analysis technique of the Stokes profiles, have been able to infer the variation with optical depth of the vector magnetic field and the line-of-sight velocity from an accurate spectropolarimetric map of a sunspot (see POLARIMETRY: SPECTROPOLARIMETRY). In this work, evidence has emerged that the Evershed effect (as well as the sunspot magnetic field) does not stop at the visible penumbral boundary in the lowest observable optical layer (in which the CONTINUOUS SPECTRUM is formed). Moreover, they found a strong correlation (almost all around the sunspot) between the velocities and the magnetic field inclination: blueshifts (upflows) are mostly located in the inner–middle penumbra where the magnetic field is pointing upwards, while redshifts (downflows) are mostly seen in outer zones, both inside and well outside the outer penumbral rim, where the vector magnetic field points downwards (see figure 2). A rough account of the mass flux inferred from their results yields an approximate mass conservation (within a factor 2 at maximum). Besides, their results at middle optical depths of the photosphere agree fairly well with those reported in former analyses of the problem which were unable to extract the information from the lower layers, codified in the observed Stokes profiles.

After all these modern observations a more coherent picture of the photospheric Evershed effect emerges as depicted in the cartoon of figure 3. Most of the mass flux

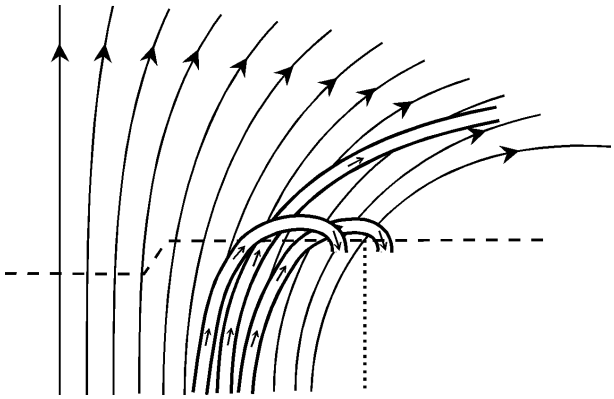

Figure 3. Cartoon (not to scale) of the (photospheric) penumbral structure with the Evershed flow channels (thick tubes with small arrows). The large-arrowed lines represent the magnetic field lines. The dashed line indicates the optical depth unity surface. The outer penumbral rim is marked with the dotted line. Adapted from *Nature* (Westendorp-Plaza *et al* 1997).

is carried through arched magnetic flux tubes that re-enter the surface at the lower layers of the outer sunspot border (either inside or outside it). Some of the mass—but a much less significant fraction—follows less arched flux tubes that extend through the superpenumbral canopy, whose outer footpoints are likely to be located farther beyond the

spot. At even higher layers, not represented in the figure, the inverse (chromospheric) Evershed effect takes place.

The physical mechanism

In the mid-1960s two prominent physical mechanisms were proposed to explain the observed Evershed effect (see references in Thomas (1994) and Maltby (1997)), namely, the siphon flow hypothesis and the wave hypothesis. In the first model, the gas is driven through an arched magnetic flux tube in whose ending footpoints a pressure difference is established: the gas flows from the higher-pressure footpoint to the lower-pressure one. This pressure difference must be produced by the different values of the magnetic field strength at the two ends of the tube: the existence of a magnetic field introduces a magnetic pressure which is proportional to the square of the field strength; hence, the flow is driven from the lower to the higher field strengths. This provides a very simple and neat explanation for the inverse Evershed effect as is currently accepted (Thomas 1994, Maltby 1997): high-lying (chromospheric) tubes connect the umbra (with an intense magnetic field) to the photosphere or other flux tubes out of the sunspot that have a lower field strength and then the flow is directed inwards. The photospheric Evershed effect was not that clearly explained, however. Prior to the 1990s, it was difficult observationally to find flux tubes out of the sunspot with magnetic fields strong enough to consider them as the ending footpoints of an outwardly directed, photospheric siphon flow.

In the wave hypothesis, the characteristic Evershed line asymmetry would be caused by the (spatial and temporal) observational average of unresolved wave motions, i.e. there would be no true outward flows but an observational effect due to the limited resolution. Different types of waves have been proposed in attempts to fit the predictions to the whole observational evidence, but, ultimately, these models are not fully satisfactory since some of their ingredients (e.g. interface surfaces) or their predictions (e.g. horizontal wavelengths) are hardly realizables. Some other hypotheses, such as mixture between siphon flows and wave-pressure-driven flows or dynamic evolution of magnetic flux tubes in the penumbra, have very recently been proposed and need further check with observations.

Alongside wave-based models, the siphon flow hypothesis has evolved remarkably in sophistication over the last few years. Siphon flow models have recently been proposed by Thomas (1994) and Montesinos and Thomas (1997) whose predictions are in fair agreement with the observational results of Westendorp Plaza *et al* (1997) reported above, thus providing significant theoretical support for this mechanism to be the physically responsible one for the currently known facts of the Evershed effect, in both the photosphere and the chromosphere. Perhaps, apart from refining the models so that they are really able to fit the observations, the only (apparently) missing ingredient is the observational determination of magnetic fields at the outer footpoints with larger strengths than those present in the middle penumbra—where the inner footpoints are located. However, this is not a drawback in the siphon flow hypothesis since observational measurements are only able to infer values of the vector magnetic field (and of the other quantities) at given optical depths, so that the *observed* footpoints do not correspond to the same gravitational potential. Proper observational evaluations of the *geometrical* stratification of the sunspot photosphere are needed (and expected) in the near future to shed some more light on this exciting problem.

Sunspots: Moving Magnetic Features and Moat Flow

Most mature SUNSPOTS and some large SUNSPOT PORES are surrounded, at least in part, by a zone which is free of stationary magnetic field (e.g. PLAGE, network) and which exhibits a radially outward horizontal mass flow. This zone is called a sunspot 'moat'. The most notable features in the moat are small magnetic structures of mixed polarity called moving magnetic features (MMFs). These are transient phenomena that can appear anywhere in the moat but most often near the outer edge of the sunspot. They move outward, usually at a higher velocity than the average moat flow, until they either fade away or reach the outer boundary of the moat.

Both sunspots and plages are also surrounded by zones that absorb acoustic power called 'acoustic moats'. These are not covered in this article.

Figure 1 shows an example of an isolated sunspot with a well-defined moat. This was a small, mature leader spot which was slowly decaying. The magnetogram on the right shows the spot's negative polarity as black and opposite magnetic polarity as white. A broken and irregular circle of the same polarity of the spot surrounds it at a distance of about 15″ (11 Mm). This is the outer boundary of the moat. The inner boundary is the edge of the SUNSPOT PENUMBRA. The MMFs are the small patches of magnetic field of both polarities within the moat annulus.

Early investigators suggested that a moat and MMFs were associated only with decaying sunspots. However, subsequent work showed that at least a partial moat is generally present even in growing sunspots. Mature, isolated spots are more likely to have a symmetric moat geometry than young, developing spots or those in complicated active regions. The width of the moat scales with the size of the sunspot.

Properties of MMFs

MMFs are best studied in movies with the highest possible spatial resolution. In addition to the magnetic signal, they are also visible as bright features in many photospheric lines, molecular bands such as the 3883 Å CN bandhead and the wings of the Ca II H and K lines. The features are larger for lines formed higher in the atmosphere indicating a spreading with height. Very small bright footpoints are sometimes visible in the continuum and, with much more contrast, in G band images. The latter are taken in a 12 Å band heavily populated by CH lines centered at 4508 Å. In these photospheric lines they look very much like small fragments of stationary magnetic field such as plage or enhanced network. However, in addition to their characteristic motions, MMFs differ by having little or no chromospheric or coronal emission associated with them. Many aspects of MMFs are near (or below) the limits of spatial resolution imposed by atmospheric seeing. Hence many details of how they form and evolve are still lacking.

There seem to be at least three classes of MMFs that have been identified in movies. The most prominent variety (type I for reference below) begin as small magnetic bipoles that erupt from below and then gradually separate. These can appear anywhere in the moat. A second type (II) consists of unipolar features that are shed from the edge of the sunspot. These have the same polarity as the spot and have been suggested as part of the sunspot decay mechanism. A third variety (type III) are higher-speed unipolar features with the opposite polarity to the sunspot that are associated with small, bright continuum points.

Type I MMFs

The type I MMFs are the best described. The early phase is visible as a small dark area (about 1000 km) in the upper photosphere as seen in broad-band ($\approx$ 3 Å) Ca II K line movies. With less contrast, this darkening is also visible in the continuum, showing dark fibrils characteristic of emerging magnetic field (see CHROMOSPHERE: FIBRILS). Over a period of about 10–20 min, the dark area expands and elongates into a spindle shape with a brightening appearing at each end. The latter are also easily visible in broad-band K line images and probably any line formed in the upper SOLAR PHOTOSPHERE or lower CHROMOSPHERE that shows bright plage. At this stage the new MMF is 2000–3000 km in size. The bright points are typically 500 km or larger as seen in the inner K line wings but may be only 200 km or smaller in continuum or G band images which are formed deeper. Coincident with the bright points are two areas of magnetic field with opposite vertical components forming a bipole. These are assumed to be the footpoints of a magnetic loop arching between them. Before this stage, longitudinal magnetograms show little or no signal, consistent with a more horizontal field. This development of a type I MMF is shown in a set of space–time images in figure 2(*b*). The spatial part of these is a line spanning the two bright points labeled b in figure 2(*a*). The initial dark patch is labeled 1, the inner footpoint 2 and the outer 3. The edge of the sunspot is on the right-hand side of these and has negative (black) polarity.

Type I MMFs are more likely to appear near the outer perimeter of the sunspot but, as already noted, can appear anywhere in the moat. The line between the magnetic footpoints is generally within 45° of the radial direction from the sunspot. Deviations may be more common further from the spot. When near the spot they frequently appear along a continuation of a dark penumbral filament. The inner footpoint has the same magnetic polarity as the sunspot. Measurements of the longitudial magnetic field range from about 100 to 300 G but are complicated by the small size of the features. The magnetic flux for each footpoint is typically 2×10^{18} Mx with reported values ranging from 10^{18} to 10^{20} Mx.

After appearing, the two footpoints separate at approximately 100 m s^{-1} while both move outward at about 500–1000 m s^{-1} in the moat. Nearby MMFs can move at different velocities and most move outward more quickly than the overall moat flow (described below). Hence they are not just carried along by the visible surface motion in the moat. Frequently the two poles are

(*a*) (*b*)

Figure 1. (*a*) A sunspot imaged in the continuum (6328 Å) showing the umbra and penumbral regions and the surrounding granulation. (*b*) A magnetogram with the moat between the sunspot and surrounding plage indicated. This zone extends all around the spot. The MMFs are the salt and pepper features in the moat. Black is negative field and white is positive. This example is more symmetric and regular than most. Both images were taken at the Swedish Vacuum Solar Telescope on La Palma on 29 August 1993.

not equally visible and the visibility of both against the background drops after the initial phase. MMFs move outward until they either fade from view or reach the outer edge of the moat. Sometimes an interaction at the edge is visible in the form of a small brightening and/or a magnetic cancelation of the leading point. However, details are largely unknown as is the fate of those that fade from view.

Much of the magnetic field in the outer penumbra of a sunspot is nearly horizontal and a substantial fraction of it seems to re-enter the photosphere at the boundary. If filaments of this field continue to extend horizontally outward somewhere below the visible surface, then type I MMFs can be understood as upward kinks or embolisms in one of these filaments. In this scenario, they represent a recycling of magnetic flux from the sunspot and do not contribute to a loss of flux or decay of the sunspot field. The motion of this 'kink' has been modeled as a soliton wave in the magnetic filament.

Type II MMFs

Type II MMFs are only formed at the edge of a sunspot. This is a very dynamic region with continual extensions and retractions of the tips of penumbral filaments and a strong collar outflow (described below). The type IIs appear here with the same magnetic polarity as the sunspot but without any apparent connection with a nearby point of opposite polarity as with the type Is. As such they seem to represent a loss of flux from the sunspot and may be related to sunspot decay. However, it is not known whether they are more frequent in rapidly decaying sunspots. After moving into the moat, they behave and appear like a separated inner half of a type I MMF with magnetic fields and fluxes within the range exhibited by type Is.

Type III MMFs

The type III MMFs are more transitory than the other two and exist only for several minutes near the edge of a sunspot. A type III begins as a small bright point that seems to be emitted from the outer edge of the penumbral and travels outward a few thousand km at 2000–3000 m s^{-1} before disappearing. They are generally smaller than the initial bright points in type Is but often brighter in the continuum. Together with their high speed, this makes them very eye-catching in movies and they were dubbed 'streakers' when first seen in continuum movies. The magnetic polarity is opposite that of the sunspot with a smaller total flux than the type Is and IIs. The bright point seen in the continuum and G band may lead the magnetic feature slightly. They generally seem to catch up with a slower-moving type II MMF (perhaps type Is as well) whereupon they vanish, sometimes with a local brightening. The latter continues to move outward in the moat, largely unaffected by the collision and apparent merger. Figure 2(*c*) shows a space–time image of an example. The small streaker is labeled 4 and the type II MMF that it combines with is labeled 5. The path is labeled c in figure 2(*a*). The edge of the sunspot is to the left and it has negative (black) polarity.

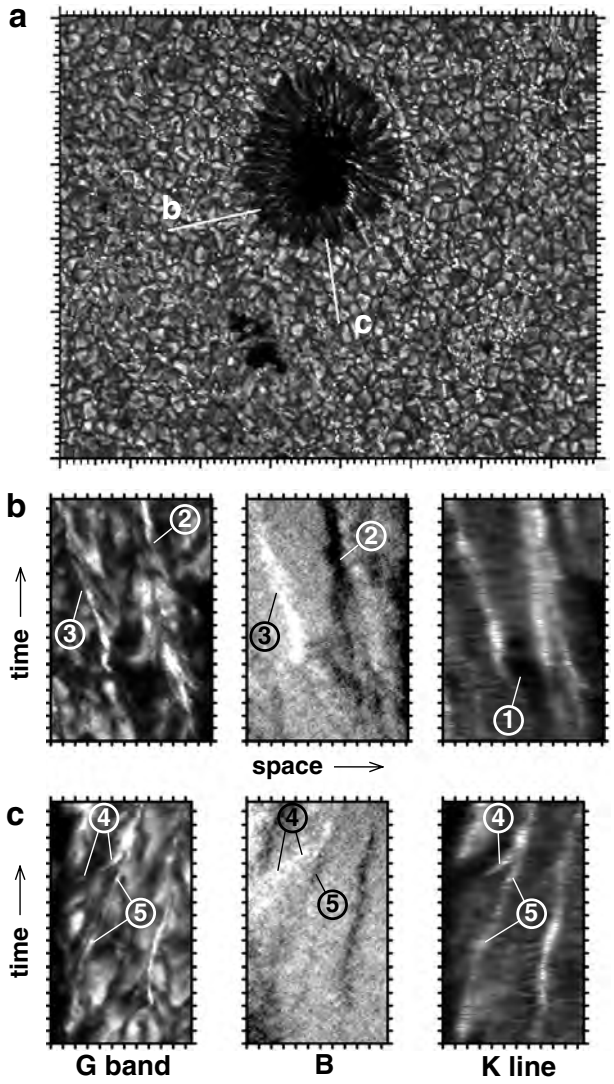

Figure 2. MMF examples. (*a*) A G band image of a sunspot showing the two paths used to construct the space–time images for (*b*) and (*c*). Tick marks are in arcsec. The left space-time images for (*b*) and (*c*) are G band intensity, the middle are magnetic field, and the right are K line intensity (3 Å wide filter). (*b*) shows a type I MMF and (*c*) shows a type III. The magnetic field is scaled from about −50 to +50 G for black and white respectively. The vertical ticks are 5 min intervals and the horizontal ticks are in arcsec. All data were taken at the Swedish Vacuum Solar Telescope on La Palma on 14 June 1994.

There may well be other types of MMFs and the *ad hoc* classification used here may not bear up as MMFs are studied in more detail. The type Is are similar to small magnetic flux eruptions seen in the interior of quiet Sun supergranules but are much more frequent in the moat (see SOLAR PHOTOSPHERE: SUPERGRANULATION).

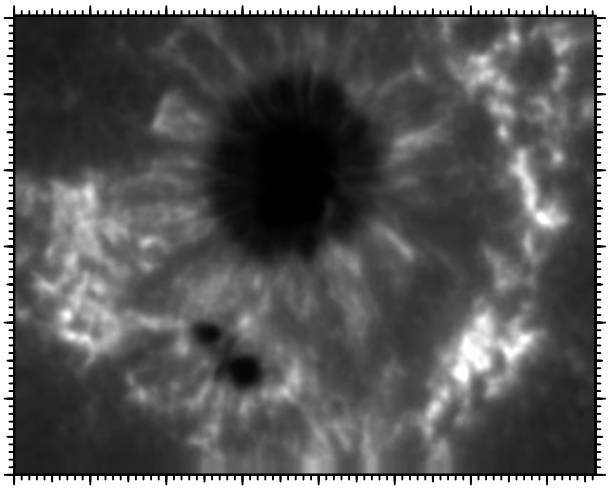

Figure 3. A 4 h average of K line images (3 Å wide filter) for the same sunspot shown in figure 2(*a*). The bright rays in the moat track the preferred paths of bright points associated with MMFs. Tick marks are in arcsec.

Moat flows

The outer radius of the moat is typically about twice that of the associated sunspot. For a large sunspot this may reach 50 Mm or more. There may be a minimum moat radius of 8 Mm for very small spots, about the size of an average supergranule. Doppler and local correlation tracking (LCT) measurements indicate an average outward flow of about 400–600 m s^{-1} with no dependence on spot size.

Just outside the sunspot penumbra, there is also a narrower region, sometimes called a 'collar' flow, with higher outward velocities than the rest of the moat. The width of this collar is about 2000–3000 km with velocities typically 1000 m s^{-1}, about twice that of the middle moat. This blends into the moat flow where the latter exists. The collar flow may extend all around the spot, however, even where there is not a larger-scale moat flow. It is distinct from the Evershed effect (see SUNSPOTS: EVERSHED EFFECT) seen in the sunspot penumbra although the two may be somehow related. The latter is seen in the dark filaments of the penumbra and has a higher velocity than the collar flow which is a motion of granulation just outside the spot.

The LCT method has been used to map details of the horizontal motions in sunspots and the surrounding moat. When applied to continuum images, it tracks the granulation pattern without any significant contribution from MMFs. On time scales of an hour or less, the pattern is dominated by motions on a mesogranular scale (4000–7000 km) just as in the quiet Sun. These can locally reduce or cancel the outward motion for a while. Longer averages show persistent azimuthal patterns in addition to the outward flow. There are rays of alternating azimuthal convergence and divergence that extend from the outer edge of the sunspot to the moat boundary. These seem to cause MMFs (and their associated bright points) to be

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

channeled along preferred horizontal rays as they move outward. Figure 3 illustrates this effect with a time-averaged image taken with a 3 Å Ca II K line filter. The bright rays emanating from the sunspot are caused by several MMFs traveling along each ray during the 4 h average.

The sunspot moat flow represents an organized horizontal flow pattern that can be much larger than a large supergranule (radius of 50 Mm versus 15 Mm). It is thought that this large-scale flow is driven by a temperature excess beneath the sunspot. The magnetic field in the sunspot inhibits the normal vertical convective energy transport, causing the spot to be dark and a buildup of excess heat in deeper layers. Horizontal transport in the form of the outflow then carries part of this excess heat outward although there is evidence that a large portion of it may be stored for at least several days. It has also been suggested that the faster motion of MMFs may represent coupling to faster subsurface flows. A completing theory for these faster motions is that MMFs represent traveling soliton waves in magnetic filaments that are otherwise below the visible surface.

Current research

Since their discovery 30 yr ago, MMFs have remained a difficult subject for observations, requiring high spatial resolution movies for at least several hours. The theory is still very rudimentary and it may well be that none of the current concepts is really correct. Detailed modeling will depend on better observations to better constrain the possibilities. Recent and future observations from the Solar Heliospheric Observatory (SOHO) and the Transition Region and Coronal Explorer (TRACE) satellites will provide material for studies in dozens of sunspots. These are only medium ($\approx$ 1″) resolution but provide uniform data sets unaffected by atmospheric seeing for several days. They will finally allow meaningful statistics to be assembled on MMFs and moat flows and their relation to sunspot evolution. Higher-resolution studies will be required to study the fine structures in MMFs and how they move within the moat faster then the general moat flow. Particularly needed are vector magnetograms to understand their detailed magnetic structure and how MMFs near the sunspot are formed. Future telescopes in space and on the ground will eventually provide these observations and the next 10 yr should see much progress in our understanding of these features.

Current and future work on three-dimensional maps of the temperatures and velocities around and underneath sunspots using helioseismology looks very promising. It should eventually provide details of the heat trapping and convective motions associated with sunspots and a clearer picture of the role of the moat flow.

Bibliography

The outward motions of bright points around sunspots were first noted by Sheeley in CN 3883 Å spectroheliograms and Vrabec discovered 'streaming flux knots'. The first systematic study of MMFs and sunspot moats is that of Harvey and Harvey in 1973. They introduced the term 'moving magnetic feature' and the MMF acronym. The earlier discovery papers are cited therein, some of which are proceedings from meetings that may be difficult to find. The term sunspot 'moat' was suggested by Dr Sheeley. Brickhouse and LaBonte reviewed moat observations up to 1985 and this remains the most thorough study published to date. A recent theory to explain type I MMFs is given in Ryutova, *et al* which also quotes earlier work and summarizes known characteristics of MMFs.

Sunspots: Wilson Effect

The Wilson effect refers to the depressed appearance of SUNSPOTS when positioned close to the solar limb. The impression is that sunspots are cavities in the SOLAR PHOTOSPHERE. The reason is that the radiation we observe is coming from deeper layers in the sunspot than in the surrounding photosphere. The detection of this depression by Alexander Wilson dates back to 1769. The phenomenon is explained, first without mathematical expressions and then in greater detail.

Detection

The phenomenon was detected by ALEXANDER WILSON, the first Professor of Astronomy in Glasgow, in 1769 and published in *Philosophical Transactions of the Royal Society* in 1774. Figure 1 is a reproduction of the essential part of one figure in his publication. Wilson started his observations of a sunspot near the western limb on 22 November 1769. He noted that the sunspot was very large and the extent of the penumbra, i.e. the medium bright region between the dark umbra and the photosphere, was equally large on the side closest to the solar limb and on the side closest to the center of the solar disk. The next day, on 23 November the sunspot was close to the solar limb (see figure 1, position 1), and Wilson noted that the shape of the penumbra on the side closest to the center of the solar disk had changed since his previous observation. The size of this side of the penumbra had decreased, whereas the penumbra closest to the solar limb was nearly unaltered. The solar rotation moved the sunspot to a location even closer to the western limb of the Sun on 24 November (see figure 1, position 2). Wilson observed that the penumbra closest to the disk center had disappeared.

In his 1774 publication Wilson discusses two possible explanations, either there was a real change in the shape of the sunspot or the sunspot was 'a vast EXCAVATION in the luminous matter of the sun'. Since digging in the solar surface sounds unrealistic we will in the following replace the word excavation by cavity or depression. Wilson knew that he could discriminate between the two possibilities if he could observe the same sunspot close to the eastern limb. Fortunately the sunspot was long-lived and reappeared with nearly the same size on the eastern limb. Wilson observed the sunspot on 11 and 12 December (see figure 1, positions 3 and 4). He saw that the shape of the penumbra closest to Sun's center was undergoing changes. However, the side of the penumbra that was changing as a function of time close to the eastern limb was the same part of the sunspot that was not affected when the sunspot was close to the western limb. Hence, he concluded that sunspots are cavities in the solar photosphere.

Explanation

In the literature on sunspots one often meets the expression sunspot darkness. It is important to realize that a considerable amount of radiation is emitted from the sunspot and that the expression sunspot darkness reflects the observation that the radiation emitted by the sunspot is less than that of the surrounding photosphere. The radiation coming from the penumbra exceeds that coming from the umbra, but it is less than the photospheric radiation. This is illustrated in figure 2 by a darker grey color in the umbra than in the penumbra (see also SUNSPOT PENUMBRA; SUNSPOT UMBRA).

Consider a circular sunspot consisting of an umbra shaped like a cylinder, surrounded by a penumbra shaped like a cylindrical sheet. The intensity levels across the umbra and the penumbra are assumed to be constants. The symmetry axis of this hypothetical sunspot is perpendicular to the solar surface. Figure 2 shows a sketch of the sunspot in a plane that contains the symmetry axis of the sunspot and the line-of-sight for an observer on Earth. Observations show small variations in intensity both within the umbra and the penumbra, but these variations are neglected here. In figure 2 the sunspot is located close to the solar limb, such that an observer on the Earth sees the sunspot under a large aspect angle. It should be pointed out that in figure 2 we have drawn the spherical surface as a plane layer, neglecting that the directions from different locations inside the sunspot and its surroundings to the center of the Sun are not parallel.

Since the Sun is a sphere of hot gas the solar surface is not solid. Therefore the important question is where the radiation we observe comes from. The intensity of the observed radiation is determined by the emission and absorption along the line of sight. Hence, several adjacent layers within a certain height interval, or distance from the Sun's center contribute to the observed radiation. Within this height interval the temperature decreases with increasing height. This implies that the emission decreases with height in this height interval, but the probability for the photons to escape and reach the observer without being absorbed is increased.

The solar radiation in visible light originates within a height interval of approximately 500 km (0.5 Mm). Since the solar radius is 696 000 km (696 Mm) this layer may be regarded as shallow compared with a solar radius. In figure 2 the picture is simplified by letting the height interval where the visible light originates be illustrated by the width of a single line dividing the solar interior from the exterior.

Since the visible light originates within a height interval determined by the emission and absorption coefficients, this interval may be centered at different heights in the umbra, penumbra and photosphere. The main ingredients of the gas, hydrogen and helium, have a low degree of ionization in the layers that contribute to the radiation. The main absorber is the negative hydrogen ion, formed by the affinity of free electrons to neutral hydrogen atoms. The free electrons are supplied by minor constituents of the gas, such as iron, with a lower ionization potential than hydrogen. With increasing temperature, the number density of free electrons increases, the density of negative hydrogen

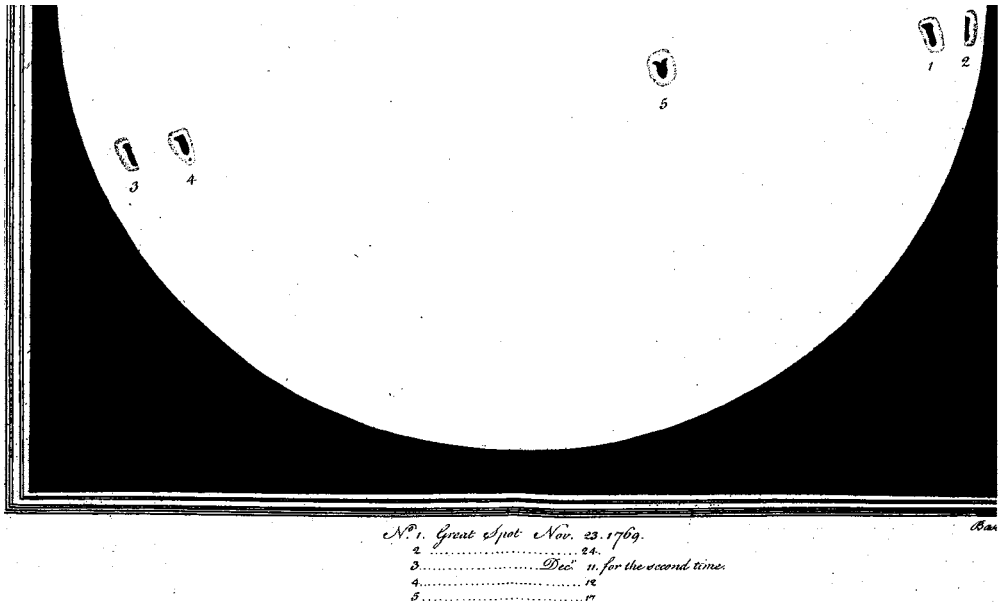

Figure 1. Copy of Alexander Wilson's drawing of the large sunspot he observed in 1769.

ions increases, the absorption coefficient increases, and the corresponding solar feature becomes less transparent. We know that the temperature of the penumbra is higher than the umbral temperature, but lower than the photospheric temperature. This implies that the umbra is more transparent than the penumbra and the penumbra is slightly more transparent than the surrounding photosphere. In order words, we 'see' to deeper layers in the umbra than in the penumbra and to slightly deeper layers in the penumbra than in the photosphere. In a more stringent discussion the possible differences in density between the umbra, penumbra, and photosphere must be taken into account. It follows that the umbral radiation originates at a lower height.

Recall that in figure 2 the dividing line between the solar interior and exterior is taken to represent the height interval where the visible radiation originates. To illustrate that we observe radiation coming from different heights figure 2 shows that the radiating layer is located higher in the photosphere than in the penumbra and considerably higher than in the umbra. For illustrative purposes the height differences between the umbra, penumbra and photosphere are exaggerated. The height difference between the umbra and the photosphere, called the Wilson depression, is of the order of 500 km. Hence, it is comparable with the height interval that contributes to the visible radiation.

With these height differences in mind consider an observation of a sunspot located close to the solar limb. Since the penumbral radiation originates at a lower height than the photospheric radiation, the photosphere will obscure part of the penumbra on the side of the sunspot

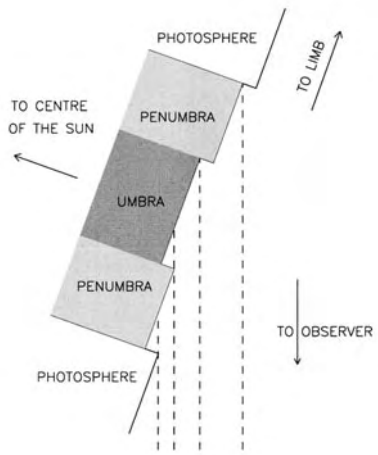

Figure 2. Sketch of a circularly shaped sunspot located close to the solar limb.

remote from the limb. In figure 2 this part of the sunspot is located in the lower half of the sketch. The penumbra closest to the limb, on the other hand, will not be obscured (see figure 2). Since the umbral radiation originates in layers located deeper than the layers contributing to the penumbral radiation, part of the umbra will be obscured by the penumbra. Hence, the size of the umbra will decrease (increase) faster than expected from perspective foreshortening as the sunspot is moved by solar rotation towards (away from) the solar limb. This simple model describes the main characteristics of the Wilson effect.

Most sunspots change their shape from one day to

the next, and the fraction of sunspots with a lifetime comparable with the sunspot shown in figure 1 is minute. These factors explain why it is difficult to measure accurately the Wilson depression. An interesting way of estimating the magnitude of the Wilson depression is based on measurement of solar rotation (see Balthasar and Wöhl 1983; SOLAR INTERIOR: ROTATION). Consider the determination of solar rotation from (a) sunspot positions during their passage over the solar disk and (b) the time difference between two successive passages of the same sunspot across the same position on the solar disk. The latter method is independent of the Wilson depression, whereas the first method depends on its value. The reason for this dependence may be understood by comparing the apparent positions of two sunspots, one with and one without Wilson depression. The sunspot without Wilson depression will be at the same height as the photosphere and located closer to the limb than a sunspot with depression. On the basis of such observations values between 500 and 1000 km have been found for the Wilson depression.

Towards a model calculation

It was suggested by Bray and Loughhead (1964) that a sufficient condition for a SUNSPOT MODEL to show a Wilson effect is that the transparency increases from the photosphere through the penumbra to the umbra. However, Jensen and Maltby (1965) showed that the most transparent umbral models lead to marked intensity peaks on the limb side of the umbra. Such peaks are never observed. Jensen *et al* (1969) neglected the pressure and density variations across both the umbra and the penumbra and approximated a sunspot by placing models of the umbra, penumbra and photosphere side by side. Furthermore, they assumed that each model could be determined from the hydrostatic equation $\nabla P = -\rho g$, where P is the gas pressure, ρ is the density and g the gravitational acceleration. To be able to compare the results with observations they constructed a series of models and calculated the specific intensity, I_λ, for different values of the wavelength, λ, and the aspect angle, θ, by the expression

$$I_\lambda = \int_0^\infty S_\lambda(t_\lambda)\, \mathrm{e}^{-t_\lambda}\, \mathrm{d}t_\lambda$$

where the source function, $S_\lambda(t_\lambda)$, was approximated by the Planck function. Special care was taken in calculating the optical length, t_λ, along the ray making an angle θ with the surface normal. The optical length differs from the optical depth divided by the cosine of the aspect angle when the ray passes from, say, the photosphere into the penumbra. They found that a Wilson depression of 400 km could satisfy the available observations.

Observations show that sunspots have strong magnetic fields. The darkening of the sunspot depends on this field, as may be illustrated as follows. Consider a time-independent case and write the momentum equation as

$$\rho \boldsymbol{v} \cdot \nabla \boldsymbol{v} = -\nabla P - \rho \boldsymbol{g} + \boldsymbol{j} \times \boldsymbol{B}$$

where ρ is the density, $\boldsymbol{v}$ is the velocity, P the gas pressure, $\boldsymbol{g}$ the gravitational acceleration and $\boldsymbol{B}$ the magnetic induction. Neglecting the displacement current, the current density $\boldsymbol{j} = \frac{1}{\mu_0} \nabla \times \boldsymbol{B}$, where μ_0 is the permeability.

In layers close to the solar surface most velocities are subsonic and the darkening of a sunspot is mainly determined by the magnetic field (see SUNSPOT MAGNETIC FIELDS). In the simple case where the effect of the velocity field is neglected and the magnetic field is axisymmetrical without an azimuthal component, the momentum equation in cylindrical coordinates reads

$$\frac{\partial P}{\partial r} = \frac{B_z}{\mu}\left(\frac{\partial B_r}{\partial z} - \frac{\partial B_z}{\partial r}\right)$$

$$\frac{\partial P}{\partial z} = -\rho g - \frac{B_r}{\mu}\left(\frac{\partial B_r}{\partial z} - \frac{\partial B_z}{\partial r}\right).$$

Integration of the first equation from the center ($r = 0$) of the sunspot to the photosphere ($r = a$) gives the difference in gas pressure

$$\begin{aligned} P(r=a) - P(r=0) &= \frac{1}{2\mu} {B_z}^2(r=0) + \frac{1}{\mu}\int_0^a B_z \frac{\partial B_r}{\partial z}\, \mathrm{d}r \\ &= P_M + P_T. \end{aligned}$$

Thus, the lower gas pressure in the sunspot than in the surroundings is caused by the magnetic pressure, P_M, and the tension, P_T, in the magnetic field. Close to the surface the magnetic field fans out and the tension must be taken into account. With the help of the equation of state for an ideal gas we may proceed to deduce the ratio between the temperature $T(r = 0)$ in the center of the sunspot to the photospheric temperature, $T(r = a)$, at the same height z

$$\frac{T(r=0)}{T(r=a)} = \frac{m(r=0)}{m(r=a)} \frac{1 - \frac{1}{P(r=a)}(P_M + P_T)}{1 + \frac{H(r=a)}{P(r=a)} \frac{\partial}{\partial z}(P_M + P_T)}$$

where the average molecular weight is $m(r = 0)$ in the center of the sunspot and $m(r = a)$ in the photosphere. $H(r = a)$ is the pressure scale height in the photosphere. For a homogeneous magnetic field the expression reduces to $T(r = 0)/T(r = a) = 1 - B^2/(2\mu P(r = a)) = 1 - P_M/P(r = a)$. Following similar arguments magnetostatic models for the whole sunspot have been presented and recently the velocity field has been included in the calculation with the aim of developing a dynamical model for the penumbral fine structure and the flow field in sunspots. Hitherto these models have not been extended to include calculations of the emitted radiation across the sunspot.

Sunyaev–Zeldovich Effect

The Sunyaev–Zeldovich (SZ) effect is a spectral effect on the COSMIC MICROWAVE BACKGROUND (CMB) caused by interaction with the electrons in the hot gas inside a CLUSTER OF GALAXIES. In the Rayleigh–Jeans portion of the spectrum it manifests itself as a small ($\sim$0.5 μK) dip in the temperature of the CMB in the direction of the cluster. First proposed in 1970, about 20 yr of observational effort were required before it was reliably detected. Many tens of clusters have now detected in the SZ effect, and early predictions of its usefulness for cosmology are now starting to bear fruit.

The basic mechanism of the SZ effect (see figure 1) involves scattering of CMB photons by electrons in the distributed intracluster gas that exists in clusters of galaxies and in fact makes up about a quarter of their total mass. A rich cluster may have a total mass $>3 \times 10^{14} M_\odot$ and gas in hydrostatic equilibrium in the potential well of the cluster heats to temperatures of order 10^7–10^8 K. The hot electrons in this plasma have two effects: firstly they produce thermal bremsstrahlung radiation, which provides the cluster x-ray luminosity. Secondly, they interact with CMB photons passing through the cluster, via Thomson scattering. This preferentially increases the energy of the photons involved in the scattering, giving an effective shift of the CMB BLACK-BODY RADIATION curve to higher frequencies and hence a dip in the Rayleigh–Jeans region of the spectrum, and an increment in the Wien region. (The precise form of the temperature shift as a function of frequency is shown in figure 2.) The magnitude of the effect is proportional to the line integral of electron pressure through the cluster, and hence directly proportional to electron number density, n_e, and temperature. This is in contrast to the thermal bremsstrahlung responsible for the x-ray emission, which is proportional to n_e^2. This difference makes the SZ effect more sensitive to the broadly distributed component of gas, rather than the dense central regions favored in x-ray emission. A further, very useful, aspect of the SZ effect is that for the same physical gas parameters it is independent of REDSHIFT. This makes it as easy to detect at high redshift, where optical or x-ray detection of a cluster may be very difficult, as at low redshift, thus making it a useful cosmological probe. In addition, the combination of x-ray and SZ data on a cluster makes possible a determination of the HUBBLE CONSTANT independent of the usual distance ladder techniques. The results for H_0 from this method are already of interest and are expected to be of increasing importance in the future, as both the systematic and the random errors in the technique start to decrease.

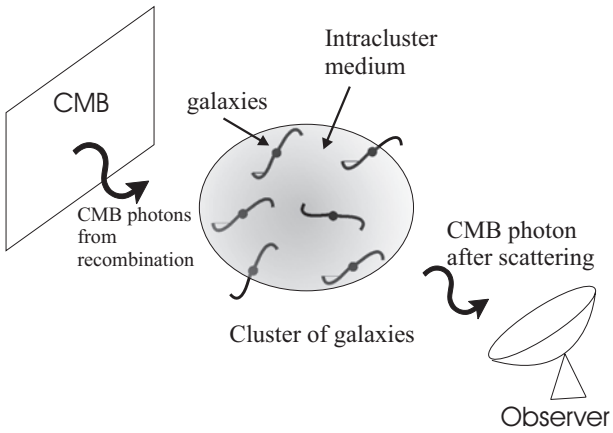

Figure 1. Schematic showing the origin of the SZ effect. Hot intracluster gas in a cluster of galaxies gives a small increase in the net energy of CMB photons arriving from the early universe.

The physics of the Sunyaev–Zeldovich effect

Probably the best way to derive the SZ effect, including relativistic corrections, is in the context of an extended version of the *Kompaneets equation*—this is discussed further below. We first begin with a heuristic derivation: consider the injection of energy, via Compton scattering, from an electron gas into an isotropic photon gas. We shall suppose that the electron gas is non-relativistic and with no bulk motions and that the radiation temperature $T_{\rm rad}$ is $\ll$ the electron temperature T_e. (This is well satisfied in practice.) With these conditions it is not immediately obvious that there should be any effect—if the scattering is elastic, then one cannot change the basically isotropic distribution of photons or electrons. It is true there is a 'Doppler scattering' effect

$$\frac{\Delta\nu}{\nu} = \frac{v_e}{c} \times \text{angular factor}$$

where v_e is the velocity of the colliding electron, but this will average to zero, since the electron velocities are isotropic. (Note that this formula will tell us what happens when there *is* a bulk motion.) The SZ effect arises as follows. The scattering mechanism is Thomson scattering, for which we know

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \sigma_T \frac{3}{16\pi}(1+\cos^2\theta)$$

where θ is the angle between the photon and electron directions, i.e. there will be maximum scattering in the forward and backward directions. We therefore approximate the problem as one-dimensional and consider in the cosmological (photon gas) frame the head-on collision of a photon with energy $h\nu$ with an electron with a velocity $v = \beta c$ directed away from the incoming photon. In the electron rest frame the photon energy is transformed to $h\nu[(1-\beta)/(1+\beta)]^{1/2}$ and there is an equal scattering probability in the forward and back directions. In these directions there is no frequency shift, from the familiar Compton formula

$$\lambda' - \lambda = 2\lambda_e \sin^2(\theta/2) \qquad \lambda_e = \frac{h}{m_e c}.$$

Transforming back to the cosmological frame we find that the photon has energy $h\nu(1-\beta)/(1+\beta)$ (i.e. *red*shifted)

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

if its direction has been reversed in the encounter, or $h\nu$ if not. Now suppose that the photon came from the other direction, so that initially in the photon's frame the electron velocity was directed towards it. In this case the same analysis yields a *blue*shift to an energy of $h\nu(1+\beta)/(1-\beta)$ if the photon direction is reversed and a constant energy of $h\nu$ if not. The mean frequency after collision for photons with momentum parallel to electron velocity is thus

$$\nu' = \nu\frac{1}{4}\left(2+\frac{1-\beta}{1+\beta}+\frac{1+\beta}{1-\beta}\right) = \frac{\nu}{1-\beta^2} \approx \nu(1+\beta^2).$$

Thus there is a net second-order effect.

What happens in the interval of time Δt? Restoring the three-dimensional dependence on scattering angle, the mean shift is

$$\langle \text{probability of shift in} \Delta t \times (\beta\cos\theta)^2\nu\rangle$$

averaged over the isotropic photon momentum distribution, i.e.

$$\mathrm{d}\nu = \frac{1}{3}n_e\sigma_T c\Delta t\nu\frac{3kT_e}{m_ec^2}.$$

(Here $(n_e\sigma_T)^{-1}$ is the photon mean free path.) Thus

$$\frac{1}{\nu}\frac{\mathrm{d}\nu}{\mathrm{d}t} = \left(\sigma_T c n_e\frac{kT_e}{m_ec^2}\right).$$

The right-hand side has dimensions of (time)$^{-1}$ and we write it as $\mathrm{d}y/\mathrm{d}t$. Integrating, we obtain

$$y = \int_{t_i}^{t_f}\sigma_T c n_e\frac{kT_e}{m_ec^2}\,\mathrm{d}t.$$

The quantity y is called the Comptonization parameter and here is worked out for the case of injection of energy from an initial time t_i to a final time t_f. Equating this to the time taken for a photon to traverse a cluster yields the final formula

$$y = \int \sigma_T n_e\frac{kT_e}{m_ec^2}\,\mathrm{d}l$$

or $y = (\sigma_T k/m_ec^2) \times$ line integral of pressure through cluster. The equation

$$\frac{1}{\nu}\frac{\mathrm{d}\nu}{\mathrm{d}t} = \frac{\mathrm{d}y}{\mathrm{d}t} \qquad \text{implies} \qquad \nu(t) = \nu(0)\mathrm{e}^y.$$

In the cluster case we have $\nu_{\text{out}} = \nu_{\text{in}}\mathrm{e}^y$. This shift in frequency yields an apparent *deficit* in the Rayleigh–Jeans region of the CMB spectrum and an increase in the Wien region (see figure 2). We have

$$\begin{aligned}\Delta I(\nu) &= I\left(\frac{\nu}{\mathrm{e}^y}\right) - I(\nu) \qquad \text{generally}\\ &= 2\left(\frac{\nu}{\mathrm{e}^y}\right)^2\frac{kT_{\text{rad}}}{c^2} - \frac{2\nu^2kT_{\text{rad}}}{c^2}\\ &\qquad \text{in the Rayleigh–Jeans region}\\ &\approx I(\nu)\times(-2y) \qquad \text{for small } y.\end{aligned}$$

For a rich cluster, taking the parameters of the COMA CLUSTER as an example, $l \sim 3$ Mpc, $n_e \sim 10^3$ m^{-3} and $T_e \sim 7\times10^7$ K. Thus a typical y is 7×10^{-5}, making the assumption of its smallness in general well justified.

The result just quoted for the Rayleigh–Jeans region is the correct one (neglecting relativistic corrections), as is the general idea of a decrement in the Rayleigh–Jeans region and an excess in the Wien region. However, our derivation has ignored several important physical factors, in particular that the photon energy $h\nu$ varies after collision in the electron frame, that the photons are not isotropic in the electron frame and that photons are bosons, the latter implying that there is stimulated emission also to consider. Putting all this together to find the correct equation yields the Kompaneets equation. The general solution as a function of frequency, expressed in terms of Rayleigh–Jeans brightness temperature ($T_{\text{RJ}} = (\lambda^2/2k)I$), is

$$\Delta T_{\text{RJ}} = \left(\frac{x}{\mathrm{e}^x-1}\right)^2 e^x\left(x\coth\frac{x}{2}-4\right)yT_{\text{rad}}$$

where y is as above and $x = h\nu/kT_{\text{rad}}$. This is what a typical heterodyne system would measure. If we were to measure *flux* rather than temperature, i.e. use a bolometer-type system, then

$$\Delta I \propto \nu^2(\Delta T_{\text{RJ}})_{\text{equiv}} \propto x^2 \times \text{above}.$$

The importance of this is that the effect is thus much increased in the sub-mm region, where we are likely to be using bolometer techniques anyway. The relevant curves are shown in figure 2, which also shows the same curves for a simple change in the black-body temperature of the CMB, such as would be relevant to primordial perturbations. One can see from figure 2 that observing the flux effect in three regions, centered at approximately 2 mm, 1.2 mm and 0.8 mm say, would give a unique signature for the SZ effect, separating it quite distinctly from any anisotropies due to primordial perturbations. Pursuing this point of different frequency dependences further, we note that if a cluster has a systemic *radial* velocity then the bulk electron flow induces Doppler scattering with magnitude given by the bulk motion formula above:

$$\frac{\Delta T}{T} \sim \frac{v_{\text{pec}}}{c}\tau$$

where τ is the optical depth to Thomson scattering through the cluster, $\tau \sim \int n_e\sigma_T\,\mathrm{d}l$. The frequency dependence of this effect will be that of the black-body curves of figure 2, and so by observing at the peak of the black-body curve one can separate the direct 'thermal' SZ effect, which nulls here, from the kinetic or 'Doppler' one, which has a peak here (when measured in terms of flux). To see what the hopes are of being able to map the peculiar velocity field of clusters in this way, we take the τ appropriate to the Coma cluster, ∼1%, and assume a cluster velocity of 600 km s^{-1}, which may not be untypical of the higher velocities which could be expected. This yields a black-body temperature change of 0.05 mK. For comparison,

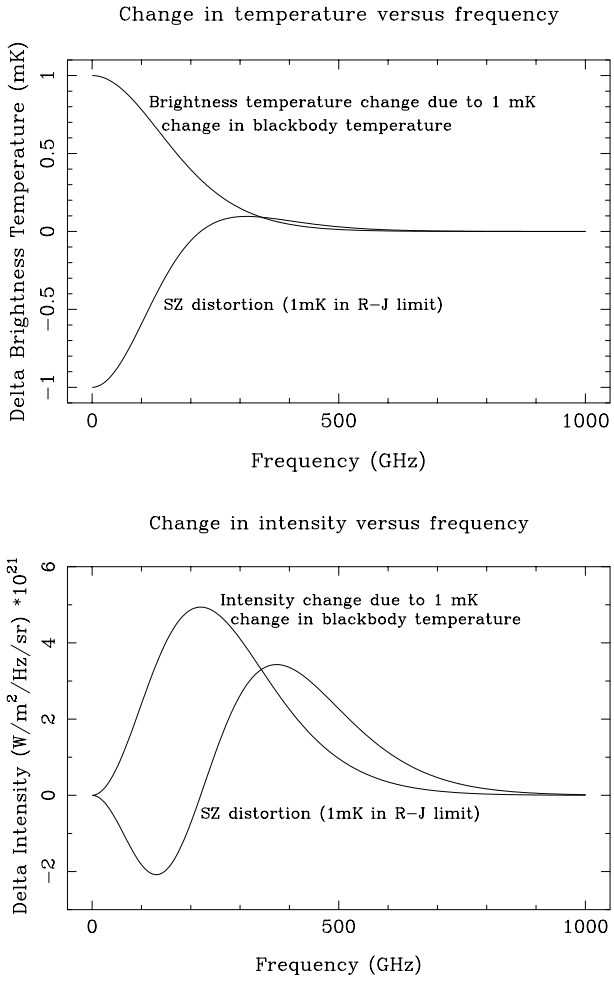

Figure 2. Top: Plots of ΔT (brightness temperature) for a 1 mK change in black-body temperature (top curve) and due to the SZ effect with a Rayleigh–Jeans limit of 1 mK. Bottom: Same but for intensity distortion.

taking the Coma cluster as an example again, the direct SZ effect expected is 0.5 mK, and indeed the measured values in several clusters appear to be of this order. Thus the mapping of the peculiar velocity field of clusters will be a difficult task, but the numbers do not look hopeless. Transverse motions of clusters also give a perturbation to the CMB via the 'moving lens effect', with a distinctive polarization signature, but for similar velocities the $\Delta T/T$ effect tends to be a few $\times 10^{-6}$ rather than a few $\times 10^{-5}$ as for the thermal and radial kinetic effects. The angular scale of the SZ effect on the sky is set by the angular diameter subtended by the cluster, and is typically a few arcminutes.

Relativistic effects

For clusters with electron temperature above about 10 keV, relativistic effects neglected in the usual Kompaneets equation must be introduced, if one wishes to match theory and experiment together properly, even at the accuracy level of the current observations, and certainly for future observations. First calculations of the corrections were made numerically by Wright and Raphaeli and recently Challinor and Lasenby have found an analytical extension of the Kompaneets approach, which allows results to be derived as power series in the electron temperature parameter $\theta_e = k_B T_e/m_e c^2$. As an example, in the Rayleigh–Jeans region, one finds

$$\frac{\Delta T_{\rm RJ}}{T_{\rm rad}} \approx -2y\left(1-\frac{17}{10}\theta_e\right)$$

to first order in θ_e. To give an example of the magnitude of this effect, for typical cluster parameters ignoring this correction would give an overestimation by about 5% in the value of the Hubble constant derived via the SZ route (described below). For clusters with temperature greater than about 10 keV there are substantial modifications to the frequency dependence of the SZ effect in the Wien region of the spectrum (by tens of per cent even at 15 keV) and the correct relativistic formulae (including θ_e^2 corrections) must be used.

Observations

A variety of approaches have been used to try to detect and measure the SZ effect. Here we highlight the techniques that have been used, roughly in order of their historical appearance.

Single-dish observations

The effect was first claimed to have been discovered by Parijskij, in 1972, in the Coma cluster. This was unlikely given the frequency of observation and the fact that Coma has a strong cluster halo source, in addition to other radio sources near the center. There were further claims in 1978 and 1981 for a detection in several clusters by Birkinshaw, Gull and Northover, using a dish at Chilbolton, UK, at 10 GHz, but again radio source confusion and possible systematic effects in the observations make it unlikely the the decrements seen (at about 1 mK amplitude) were real. The first reports of a detection that are widely believed, and seem to have withstood the test of further accumulation of data, came from Birkinshaw, Gull and Hardebeck in 1984, using the 40 m Owens Valley dish of Caltech, at 20 GHz. It might be wondered why there is any difficulty or question about these measurements, given that the effects are about 10 times bigger than a 95% confidence blank sky limit which had been set with the same telescope in a search by Readhead *et al* for primordial CMB anisotropy. The answer lies in the (necessarily) different observing strategies adopted in the two cases. For the intrinsic anisotropy work, Readhead *et al* were able to minimize telescope movement by working with fields very close to the north celestial pole and observing only near transit. For observations of specific clusters, there is no such option, since the cluster must be followed around an appreciable portion of the sky in order to build up sufficient sensitivity. This leads to two problems. First, the combination of

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

telescope on–off motions and beamswitching used for both experiments in order to reduce atmospheric effects can still leave residual systematics due to incomplete subtraction of sidelobes of the two beams. This is known as 'differential spillover'.

The second problem is that, as the source sweeps around the sky, the 'off' beams themselves sweep over circular arcs, displaced from the cluster center by the beamthrow. If these 'reference arcs' contain radio sources, these will produce negative dips in the central signal as the beams pass over them, leading to a false impression of a decrement having been detected. The only solution to this is an independent survey for the confusing radio sources. To achieve sufficient sensitivity in such a survey requires the power of the Very Large Array, but the area that needs to be covered for each cluster means that several VLA fields need to be mosaiced together, requiring quite large amounts of observing time.

Bolometer measurements

A bolometric system is able to achieve great sensitivity by having a very large fractional bandwidth and working at high frequencies. The disadvantage is that they are strongly affected by the atmosphere at these high frequencies and so have to be run from mountain tops, balloons (which have only limited observation time) or space.

The first really successful ground-based bolometer measurements have come from the Caltech SuZie group, working on the Caltech Submillimeter Observatory in Hawaii. They use a differencing bolometer scheme, coupled with drift scans across the source, which provides good stability and rejection of atmospheric fluctuations. The wavelengths observed are 1.2, 1.4 and 2.2 mm, which are properly spaced to make an attempt at separating the kinetic and thermal SZ effects. So far only upper limits have been found for the cluster peculiar velocities, but it is quite possible this instrument will be the first to detect non-zero velocities in the future. Scans at high signal to noise have been obtained on several clusters including A2163, which is the hottest known ($T_e \sim 14$ keV), making it necessary to use the correct *relativistic* formulae for the frequency dependence and amplitude of the SZ effect. Lamarre *et al*, using a balloon-borne bolometric system called PRONAOS, have made a determination of the spectrum of A2163 extending all the way to far-IR wavelengths (see figure 3), and in conjunction with the SuZie results this shows convincing evidence for the full expected frequency dependence of the SZ effect, albeit mixed in with dust emission at higher frequencies.

Interferometers

Interferometers provide currently provide the cleanest technique for making *images* of the SZ effect. An interferometer consists of a set of baselines formed by taking the elements of the interferometer in pairs. Each baseline is sensitive to a particular Fourier component on the sky and is relatively *in*sensitive to atmospheric

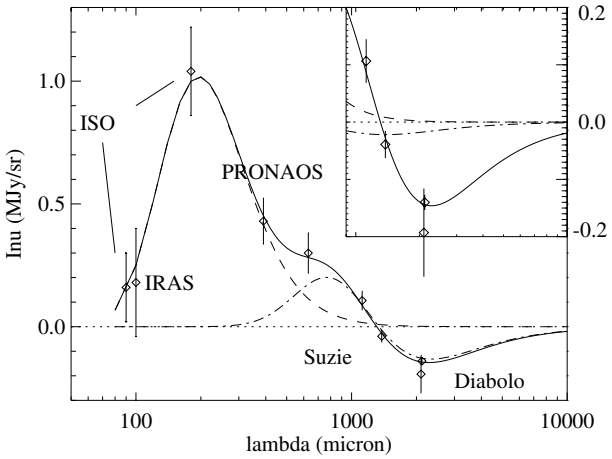

Figure 3. Spectrum of A2163, from Lamarre J M *et al* 1998 *Astrophys. J.* **507** L5. The solid curve shows a best-fit model including both the SZ effect (dot–dash curve) and predicted dust emission (dashed). The inset shows the expected contribution from the the kinetic SZ effect while the names are of the experiments used to trace different regions of the spectrum.

fluctuations and ground spillover and pickup (the problems which bedevilled earlier attempts to measure the SZ effect). Furthermore, close-in baseline pairs can be used to give a map of the SZ effects, while longer baselines can be used to subtract the effects of discrete radio sources, which are often variable, making it very desirable to measure them simultaneously with the SZ measurements. Two groups in particular have been pursuing this approach. The first image of the SZ effect came from the Ryle Telescope at Cambridge, UK, in 1993, and subsequently about 10 other clusters have been detected and mapped. In figure 4 a map is shown of the cluster A1413 made with the Ryle Telescope (Cambridge). The more centrally condensed nature of the x-ray emission versus the SZ effect is evident. The other group actively pursuing this approach have been using the OVRO and BIMA millimeter arrays in California, but with centimeter wave rather than millimeter wave receivers fitted. The lower observing frequency gives them sensitivity on angular scales appropriate to the SZ effect and they are able to use otherwise fallow summer observing periods to conduct the measurements. This campaign has resulted in the detection of about 25 clusters in SZ, and the highest signal-to-noise maps thus far made.

Determinations of H_0

The SZ effect can be used to determine H_0 in conjunction with x-ray information. We start with the equation for the x-ray flux:

$$S_x \propto \int \frac{n_e^2 T_e^{0.5}}{D_L^2}\, \mathrm{d}V$$

where n_e and T_e are the electron number density and temperature and D_L is the luminosity distance to the cluster. Via the x-ray and optical information we can

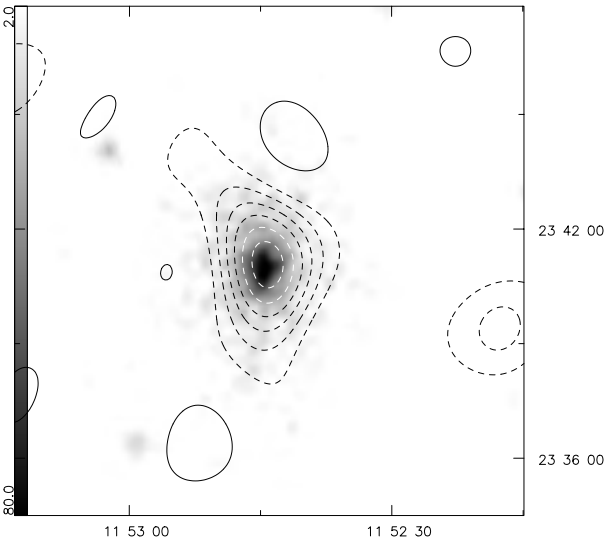

Figure 4. Ryle Telescope map of the cluster Abell 1413 (contours) overlaid on ROSAT PSPC x-ray image (greyscale). Contour levels for the radio map are −450 to 75 μJy/beam in steps of 75 μJy/beam. The numbers at the right are declination in degrees, minutes and seconds, indicating the overall angular scale. (Taken from Grainge K *et al* 1996 *Mon. Not. R. Astron. Soc.* **278** L17.)

determine T_e, θ and z, where θ is a characteristic angular size of the cluster and z is the cluster redshift. The SZ effect is determined by

$$\Delta T_{SZ} \propto \int n_e T_e \, \mathrm{d}l$$

i.e. a line-of-sight integral of pressure through the cluster, and we can relate dl to the other quantities via

$$\Delta l = \frac{f \theta D_L}{(1+z)^2}.$$

Here f is a prolateness factor, which, assuming the cluster has an ellipsoidal shape, is the ratio of the length of the major axis of the ellipse to the minor axis. The last equation uses the angular diameter distance formula to get the physical width of the cluster given its angular diameter and then converts this to a line-of-sight distance through the cluster using this assumed prolateness. This is done assuming what will turn out to be a 'worst case', where the cluster is indeed prolate and pointing straight at the observer. If we assume the cluster is at not too high a redshift, then the luminosity distance can be approximated by $D_L = cz/H_0$. (Obviously more accurate formulae can be used for this and other quantities at higher redshift.) Eliminating n_e via the known S_x, and D_L in favor of H_0, one finds

$$H_0 \propto \frac{f}{\Delta T_{SZ}^2}$$

with the constant of proportionality known. We note straightaway that if f is assumed to be 1 when it is really >1, i.e. where the cluster is indeed oriented towards the observer, then the H_0 derived by this method will come out too small. Since the H_0 values found so far using this approach have tended to come out *lower* than optical determinations, it is obviously this case that we need to worry about most in the first instance. Furthermore, for clusters which are selected on the basis of x-ray surface brightness, there would be a tendency for just this effect to happen, since the greater line-of-sight distance through the cluster would emphasize their x-ray brightness.

Putting back further factors we obtain

$$H_0 \propto \frac{f}{\Delta T_{SZ}^2} S_x T_e^2. \quad (1)$$

T_e can be found from the x-ray spectrum obtained, e.g. with the ASCA satellite, which covers the range up to ∼10 keV. A typical cluster temperature is $T_e \sim 6$ keV and ROSAT only covers the range up to ∼2 keV. The x-ray flux, S_x, can be obtained from e.g. ASCA, with resolution ∼2′, or the ROSAT PSPC, with resolution ∼15″. The cluster profile is modelled generally via an assumed isothermal atmosphere, with

$$n_e(r) = \frac{n_e(0)}{[1 + (r/r_c)^2]^{3\beta/2}}.$$

Typical values for clusters are $\beta \sim 0.6$, and core radius $r_c \sim 0.25$ Mpc, but one has to *fit* for these in any given case. For elliptical clusters, one needs to introduce different core radii along orthogonal axes. These are fitted iteratively until they match the x-ray observations. Ideally, one needs to include the physics of the pressure and cooling of the cluster in this process, and also to use simultaneously the SZ observations.

The values found so far for H_0 using this technique have encompassed a rather large range, but estimates are now beginning to stabilize. Birkinshaw, using results from nine well-measured clusters, finds a mean H_0 of 60 ± 10 km s^{-1} Mpc^{-1} (although systematic contributions to the error could be larger). Further results from the much larger samples being built up by the Cambridge and OVRO/BIMA interferometer teams are expected shortly. Carlstrom *et al*, working with detailed modeling of a single cluster, find good agreement with a value of 60 km s^{-1} Mpc^{-1} and moreover have shown that although the results for the core radius r_c and β are highly correlated after fitting, the resulting degeneracy in H_0 is quite small, which is encouraging for further work.

As well as estimating H_0, one can also use the SZ results to estimate the total baryon content of a cluster. In conjunction with information from GRAVITATIONAL LENSING in the cluster, or alternatively by assuming virial equilibrium for the intracluster material, one can then estimate the total matter fraction (baryonic plus dark) in the cluster. With a final assumption that the proportion of baryons to dark matter is similar to that pertaining in the universe as a whole, the total matter density of the universe can be found. Recently Grego *et al*, using 18 clusters from

Dirac House, Temple Back, Bristol, BS1 6BE, UK

the OVRO/BIMA sample, have obtained the estimate $\Omega_M \sim 0.23^{+0.06}_{-0.04}$ (for an H_0 of 65 ± 10 km s^{-1} Mpc^{-1}, scaling inversely with H_0 for other values). This value represents that matter fraction relative to the CRITICAL DENSITY needed to make the universe spatially flat and ties in well with other recent indications that, if the universe really is spatially flat (as primordial CMB results seem to indicate), then the deficit must be made up in some other way than via dark matter. This lends extra support to the hypothesis of a non-zero COSMOLOGICAL CONSTANT. With a sufficiently large sample of clusters out to high redshift, it may be possible to use the luminosity distance dependence of the SZ effect to measure the cosmological constant directly.

Future uses of the SZ effect

The redshift independence of the SZ effect makes it an excellent tool for investigating the evolution of structure with redshift. On the other hand, current instruments are severely limited in their ability to do the kinds of 'blank sky' searches for the SZ effect that would be necessary to fully exploit this potential, owing to their relative lack of sensitivity and the time it takes to detect just one cluster in an already-known position. Accordingly, proposals for new ground-based instruments (all interferometers), able to make maps of the SZ effect over large areas of the sky, are now being made and will, it is hoped, be funded. The 'SZ source counts' (the number of clusters per square degree with SZ effect above a certain level) are strong functions of the matter density and geometry of the universe and so should provide significant information on Ω_M. In addition, the large number of clusters detected this way could act as a 'finder' for clusters to be investigated by future x-ray missions, which will not have the same sensitivity at high redshift as dedicated SZ telescopes. As well as ground-based telescopes, some future space missions will also be able to detect large numbers of clusters via the SZ effect. The PLANCK SURVEYOR mission, due for launch by ESA in 2007, has the potential to detect tens of thousands of clusters via the SZ effect, and it is hoped that for a large number of these a detection of the 'kinetic effect' will be possible as well, thus making possible a totally new kind of mapping of peculiar velocity fields on large scales.

Superclusters and the Local Supercluster

In the 19th century, William and John Herschel noted the uneven distribution of spiral nebulae across the sky (see HERSCHEL FAMILY). In the early 1920s, J H Reynolds remarked that large non-galactic nebulae cluster along a band and 10 yr later HARLOW SHAPLEY, providing confirmation with a more systematic survey, called the flattened concentration of brightest galaxies the 'Local Supergalaxy'. Gérard de Vaucouleurs, in the 1950s, showed that locally there is a flattened distribution of galaxies with the VIRGO CLUSTER at its core and our MILKY WAY GALAXY toward the periphery. This structure has come to be called the '*Local Supercluster*'. After the mid-1970s, the effort to study the distribution of galaxies in the universe intensified and many structures similar to the Local Supercluster have now been found.

Galaxies: the building blocks of large-scale structure

It is currently believed that structure in the universe formed from the gravitational self-attraction of matter in overdense regions. Dense regions collapsed earlier in time. Probably, irregularities with high local density but low total mass formed first, then coalesced with other matter to form larger entities. Galaxies were forming and growing rapidly during the first four to six billion years in the life of the universe. All the while, galaxies were being drawn closer to each other, so they were becoming substantially clumped. The timescales for this gravitational clustering are strongly dependent on the overall properties of the universe. If the average mass density is in the vicinity of the critical density for a closed universe then galaxies are falling together in large numbers today to form large-scale structures. If the average mass density is much less than the critical density then the greatest development in the structure formation happened earlier.

In their gross properties, galaxies can be considered to be of two types. Galaxies referred to as ELLIPTICAL or LENTICULAR GALAXIES overwhelmingly contain only old stars. They have little cold interstellar gas so they lack the resources to form many new stars. On the other hand, galaxies called SPIRAL or IRREGULAR GALAXIES do contain cold interstellar gas and they have a substantial component of young stars. These galaxies can have a wide range of STELLAR POPULATIONS, from very young to very old.

Galaxies of the two types are usually found in very different environments. Ellipticals and lenticulars are found in large numbers in clusters, the densest, most congested parts of the universe. Spiral and irregular galaxies are found in filamentary structures outside the densest clusters. There are relatively few spirals or gas-rich irregulars in clusters. It is possible that those few spirals in clusters have fallen into the gravitational wells of the clusters recently. There are relatively few ellipticals or lenticulars in the low-density regions. Outside of dense clusters, most galaxies have a supply of gas for new stars.

Our own Milky Way Galaxy is a relatively large spiral galaxy. The solar system is located in the flattened disk near a spiral arm spur far out from the center.

Groups: the next level of the hierarchy

Galaxies like to be with other galaxies. Gravity pulls them together. Galaxies formed out of the self-attraction of matter in overdense regions and galaxies, in turn, are embedded in larger-scale overdense regions that collapse to form groups. Seventy per cent of galaxies are identified to lie in groups that are gravitationally bound and another 20% are found in looser associations that may not be bound. The vast majority of these groups appear to be dynamically young. Although the galaxies are usually bound gravitationally to each other, they may not have had time to make many orbits, or even one orbit, around each other. When they do approach, near collisions that cause structural disruption are not uncommon.

The dynamically young groups are predominantly populated with gas-rich spiral and irregular galaxies. There may also be swarms of dwarf spheroidal systems about big galaxies, to judge from our Milky Way situation. These DWARF SPHEROIDAL GALAXIES are so faint that they are difficult to see at the distances of other big galaxies. A small fraction, roughly 5%, of groups are predominantly populated by gas-poor ellipticals and lenticulars. These groups are dense, have higher motions and are undoubtedly more dynamically evolved.

The LOCAL GROUP is an example of a typical environment for galaxies. There are two giant spirals, Andromeda or M31 (the biggest) and the Milky Way, and two intermediate-size galaxies, Triangulum or M33 and the Large Magellanic Cloud. In total there are 40 known or suspected members but most of these are dwarfs. There are two main subgroups within the Local Group, one each around the two giant galaxies. There are two other minor subgroups around the irregular galaxies NGC 6822 and NGC 3109. The two giant galaxies contain 80% of the light of the group and are falling toward each other.

Clusters: the largest collapsed structures in the universe

Rich CLUSTERS OF GALAXIES act as nodal points in the filamentary structure of the universe. Clusters can contain hundreds of substantial galaxies and thousands of dwarfs. The total mass associated with big clusters can reach 10^{15} times the mass of the Sun. Less than 10% of this mass is directly associated with the stars in the galaxies. Of order 20% can be associated with hot hydrogen and helium gas that fills the space between the galaxies in the clusters and radiates thermal x-ray emission. Most of the mass is in an unknown form and is part of the 'DARK MATTER' problem.

The galaxies in the richest clusters are ellipticals, lenticulars and dwarf spheroidals for the most part. Spirals and irregulars fall into the clusters and over time must exhaust or be stripped of their cold gas reservoirs. Down at the center of the cluster one frequently finds a special elliptical galaxy. The central ellipticals are often

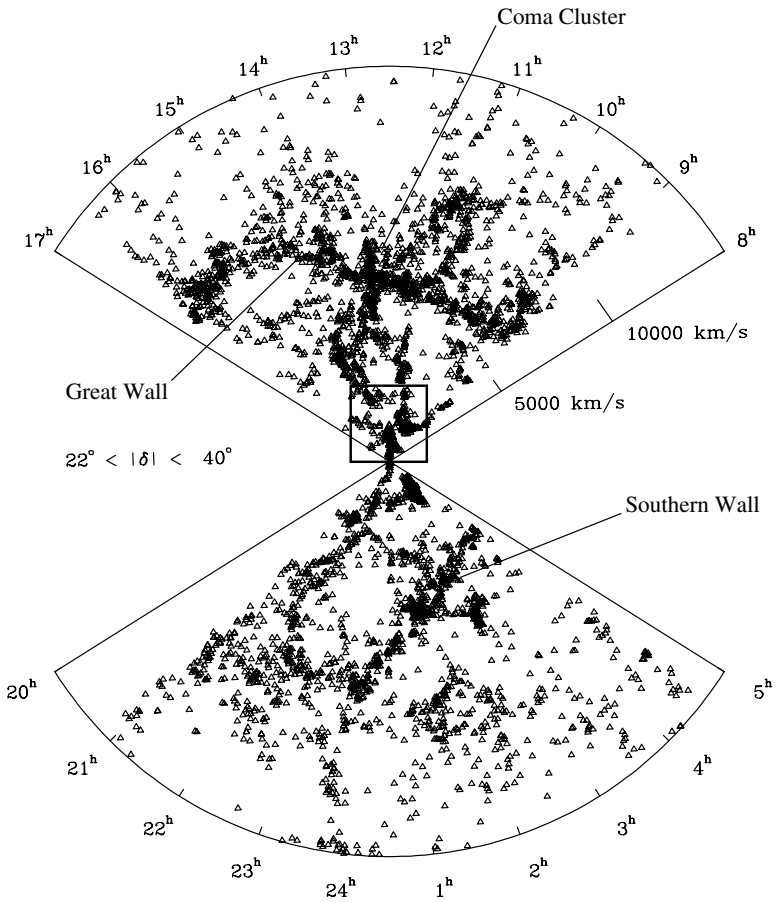

Figure 1. Large-scale structure (Luiz da Costa (European Southern Observatory), Margaret Geller (Harvard-Smithsonian), and John Huchra (Harvard-Smithsonian).

particularly large and puffed up. They probably grow through the ACCRETION of galaxies through collisions and dynamical friction. The hot intracluster gas can slowly condense onto the central galaxy through a cooling flow.

By far the most prominent nearby cluster is the Virgo cluster, usually taken as the center of the Local Supercluster. The Virgo cluster is at a distance of 16 Mpc (50 million light-years). Galaxies in a spherical region within 7 Mpc have decoupled from the expansion of the universe and are falling back onto the cluster.

The nearest rich clusters beyond the Local Supercluster are HYDRA I and CENTAURUS clusters about 2.5 times more distant than the Virgo cluster, the Perseus cluster about 4 times more distant and the particularly rich Coma cluster about 5 times more distant. There are occasional aggregates of rich clusters, such as the 'SHAPLEY CONCENTRATION' of 29 clusters at a distance of roughly 200 Mpc.

Filaments of galaxies: the cosmic web

Ninety per cent of galaxies lie outside of rich clusters in extended filaments or 'clouds'. Individual filaments are long in one dimension, often intermediate in a second dimension, and thin in the third dimension, like a flat pasta or a surfboard. Adjacent filaments can share a common plane to give the impression of a partially filled surface. Other adjacent filaments can lie in layers, analogous to window louvers.

The groups of galaxies lie like beads within the filaments. It is thought that filaments have grown through self-attraction except that collapse is only partial. Gravity has not overcome the expansion of the universe in at least the long dimension. In addition to the ∼90% of galaxies in bound groups or looser associations, about 10% of galaxies are not closely linked with other galaxies but still lie in the filaments. At most only a few per cent of galaxies lie outside these structures (see the complementary article on VOIDS).

Although not conclusively demonstrated, it is strongly indicated that filaments essentially never stand

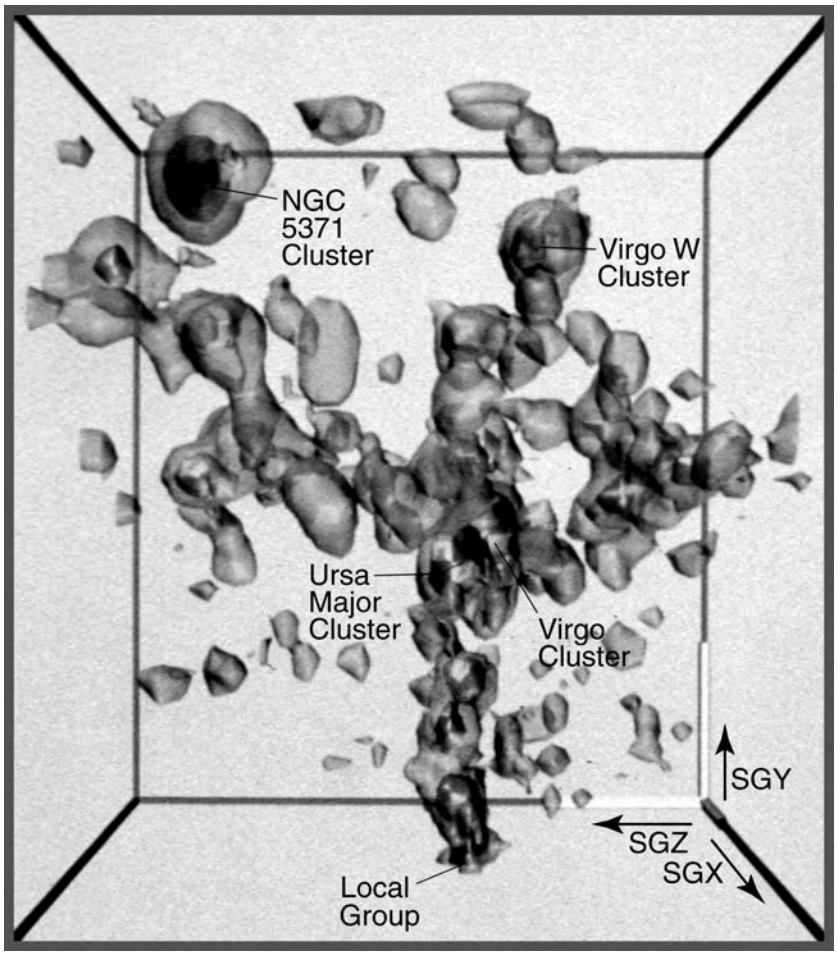

Figure 2. Detail of part of figure 1 (R Brent Tully (University of Hawaii)).

alone. Any two places in the universe that are on filaments may be interconnected by a path that runs through the network of filaments. Simulations of the formation of structure demonstrate that matter collapses onto the filaments in one or two dimensions and then drains along the filaments into the rich clusters. The simulations look subtly different in different cosmological models. If the universe will expand forever, the filaments seen today will eventually dissipate, partly by falling into the clusters and partly by the dilution that comes from continued expansion.

Galaxy flows: response to the distribution of mass

Large-scale structure is evolving. It is now appreciated that familiar objects, such as stars and interstellar gas clouds, contribute only a minor fraction to the gravitational fields that cause the formation of galaxies and structure on scales larger than galaxies. Mysterious dark matter is more important. The amount and distribution of dark matter are estimated through observations of the flows of galaxies in response to the gravitational fields.

The most certain evidence for motion comes from the dipole distribution in the COSMIC MICROWAVE BACKGROUND temperature maps. It is concluded that the Milky Way Galaxy has a motion of 600 km s^{-1} toward a well-defined position in the southern celestial sky. The motions of individual galaxies can be determined, albeit with substantial errors. It is evident that galaxies near clusters are being attracted toward the clusters and, in general, individual galaxies are being attracted toward the largest concentrations of galaxies. Overall, nearby galaxies are partaking of the motion implied by the dipole in the cosmic microwave background radiation. In principle, the amplitude of these motions provides information about the mean density of the universe. In practise, there is an ongoing dispute over the value of the cosmological density parameter that ranges over a factor of 5.

The Local Supercluster and nearby structures

The Milky Way and ANDROMEDA (M31) GALAXIES, with their entourages, reside in the gravitationally bound Local Group. At 3–4 Mpc (10–13 million light-years) away are the neighboring Sculptor, IC 342–Maffei and M81 groups.

These groups and others string along the Coma–Sculptor Cloud, a branch filament of the Local Supercluster. The Virgo cluster is the central, densest part of the Local Supercluster. The main large-scale structure in this local region is a band of galaxies that extends across half the sky through the Virgo cluster. North of Virgo, the band extends to the smaller URSA MAJOR cluster where one path of a bifurcation leads to the Coma–Sculptor cloud. South of Virgo, the band extends toward the Centaurus cluster. The flow of galaxies indicated by the cosmic microwave background dipole anisotropy is in this general direction. Viewed from afar, the historical Local Supercluster would probably be considered an appendage of a larger Hydra–Centaurus–Virgo supercluster. Recent observations in the obscured regions of the Milky Way plane suggest that the ABELL 3627 CLUSTER may be a particularly important component of this supercluster.

The next nearest important structure is on the opposite side of the sky. A prominent filament, somewhat resembling a lizard projected on the sky, runs through the constellations of Perseus and Pisces. Somewhat farther, at roughly 90° to both the Hydra–Centaurus and the Perseus–Pisces structures, running through the Coma cluster, is a structure called the 'GREAT WALL'. On the opposite side of the sky is the 'Southern Wall'. As our information becomes more complete, connections are invariably found between each of these features.

The two accompanying figures illustrate some of these structures. The large scale is shown by figure 1. Individual galaxies are represented by small triangles. The distance of any given object away from our Milky Way Galaxy is given by the radial distance away from the apex of the wedge. The units of distance are the redshift units of velocity (galaxies that are farther from us are moving away with a higher velocity). It is difficult to represent three dimensions on a flat page. In this figure one is looking at a thin wedge, with hour angle on the sky displayed as the opening angle at the apex. A small range of declination is projected to the flat page. The Coma cluster is at the densest concentration of galaxies in the upper wedge. The outstretched arms from the 'stickman' body created by the Coma cluster is the 'Great Wall'. The 'Southern Wall' is seen in the lower wedge.

The box outline in this figure shows the region which is given in greater detail in figure 2. In this case, the data have been smoothed to show contours of galaxy density. There are many galaxies in the darkest regions, fewer within the lighter contours and none in the regions outside contours. The second figure illustrates the distribution of galaxies in the Local Supercluster. The Local Group lies in the Coma–Sculptor cloud, a filament that runs in a plane over to the Ursa Major cluster and down to the Virgo cluster.

Super-Kamiokande

Super-Kamiokande (SK) found evidence for neutrino masses in 1998. The SK detector is located 1000 m underground in Kamioka mine in Japan. The detector consists of about 50 000 tons of ultra pure water which fills a 40 m tall, 40 m diameter cylindrical stainless steel tank. Cerenkov radiation produced by neutrino interactions in water is viewed with 11 146 photomultiplier tubes mounted on the inner surface of the tank. The detector is used in cooperation with about 120 physicists from 20 collaborating institutes in Japan and the US. The cosmic ray interactions in the atmosphere produce muon-neutrinos and electron-neutrinos. SK has found that almost half of muon-neutrinos change to tau-neutrinos when they travel long distances, such as a diameter of the Earth. This phenomenon, called neutrino oscillations, is realized only when neutrinos have masses and each flavor state of neutrinos is a mixture of different mass states.

Another objective of SK is a precise measurement of solar neutrinos. The observed flux of solar neutrinos is about half of the expectation from the standard solar model. The deficit may be due to neutrino oscillations and the measurement at SK would reveal properties of electron-neutrinos. One of the primary objective of SK is a search for proton decays. If found, the Grand Unified Theory, which unifies strong, electromagnetic and weak inteactions, will be proved.

The data acquisition of SK was started in 1996. The predecessor of SK, Kamiokande, observed neutrino burst from a supernova in the Large Magellanic Cloud in 1987. It was the first neutrino observation in astronomical history and initiated the dawn of a new era in neutrino astronomy.

Superluminal Motion

Superluminal motion is a term used to describe rapid systematic changes in the appearance of an astronomical object, with an observed speed $v_{\rm obs}$ that appears to be faster than the speed of light c. This phenomenon was first recognized in the early 1970s, although the possibility of very high apparent expansion speeds was recognized much earlier. It is seen at radio wavelengths in the nuclei of QUASARS and ACTIVE GALAXIES, where it is relatively common. In the 1990s, rapid motions have also been discovered in a few objects within our own Galaxy, and the first optical detection of superluminal motion in an external galaxy has also been obtained. In all cases, the apparent physical speed is calculated by multiplying the measured (apparent) angular speed by the distance to the source.

The study of time variations in extragalactic radio sources is made possible by the technique of VLBI (VERY-LONG-BASELINE INTERFEROMETRY), in which radio telescopes up to 1000s of km apart are linked together as an array to allow imaging on very fine angular scales, often less than 0.001 arcsec (1 marcsec). The earliest VLBI observations involved only two or three telescopes, and no imaging was possible. Instead, simple models comprising two or more small components were fitted to the data. These simple models yielded the first detection of superluminal motion, in the quasar 3C 279 in 1971. In the 1990s, imaging arrays such as the Very Long Baseline Array (VLBA) have allowed astronomers to track motions using images taken as often as only a few weeks apart, in the case of rapidly variable sources.

A wide range of apparent speeds is seen in ACTIVE GALACTIC NUCLEI (AGN), from more than $10c$ down to speeds which are termed 'sub-luminal' ($v < c$). The most extensive compilation of measurements by Vermeulen and Cohen (1994) lists 66 extragalactic objects for which speeds have been measured, and well over half are superluminal. Superluminal sources provide important observational evidence for extreme physical phenomena in the centers of active galaxies, and the statistics of superluminal motion have an important role to play in cosmology.

The quasar 3C 345 is one of the best-known superluminal radio sources. Figure 1 shows a series of images in which superluminal motion is found in several features in the jet simultaneously (Zensus *et al* 1995). In many sources, images at low frequency, with arcsecond-scale resolution, show extended radio features on both sides of the nucleus, supporting the belief that the jet is in fact two sided, but is invisible on one side. In a few cases, images with intermediate resolution by the very large array (VLA) show two-sided jets.

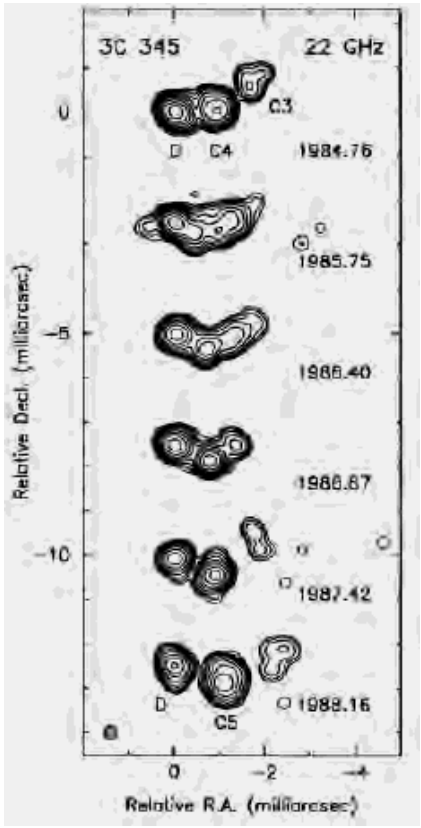

Figure 1. A series of six VLBI images of the quasar 3C 345 (redshift $z = 0.6$, corresponding to a distance of 2000 Mpc) observed over a period of 4 yr. The images are in the radio band, at a frequency 22 GHz, arranged vertically, in time order. The axes are labeled in units of milliarcseconds. A bright feature on the left side is identified as the (stationary) nucleus of the quasar and a feature on the right moves away steadily with time. The superluminal speed ranges between about $3c$ and $5c$.

Kinematic explanation of superluminal motion

The simplest, and by far the most widely accepted, explanation of superluminal motion, consistent with known physics and available astronomical data, is a phenomenon of the kinematics of moving bodies. In most superluminal sources, the motions are seen along the length of a relativistic jet which transports energy from the central engine to a pair of radio lobes. To produce an apparent speed faster than c requires (1) a true speed, in the quasar reference frame, approaching c, (2) a small angle between the jet direction and the line of sight and (3) an independent measure of the distance to the source. A distance is required because the apparent proper motion has to be converted into an (apparent) physical speed by multiplying by the distance.

Given these three conditions, the geometric relation which gives rise to superluminal motion may be explained as follows (see figure 2). At a time t_0, a quasar nucleus (N) ejects a blob of plasma (shaded dot) traveling at relativistic speed $v = \beta c$ along a 'jet' at an angle θ to the line of sight to the observer (shaded arrow). The term relativistic implies $1-\beta \ll 1$. Both the nucleus and the blob emit radio waves (black arrows), which result in the schematic VLBI images shown at the bottom, corresponding to the blob passing points B1 and B2 in the jet.

In the reference frame of the quasar, the time interval

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

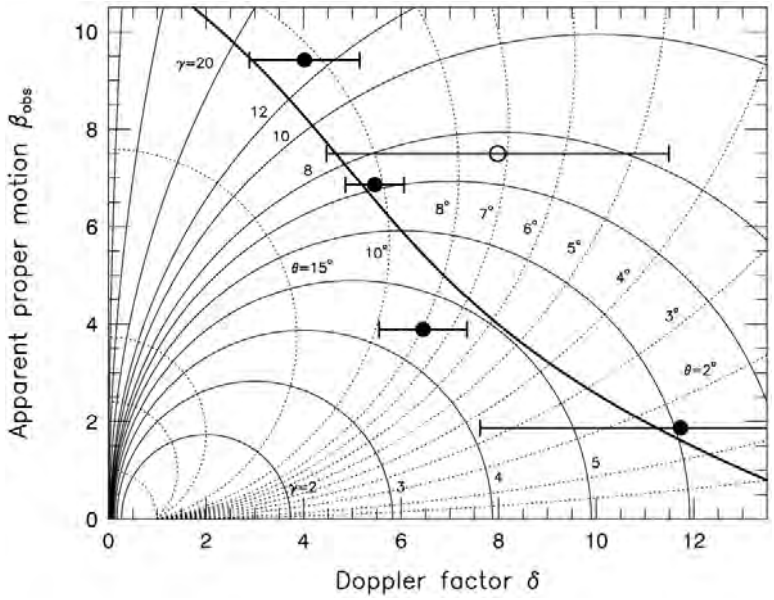

Figure 3. Kinematic parameter space of a superluminal source. The figure shows contours of constant jet angle to the line of sight θ and Lorentz factor γ of the relativistic jet flow. The axes represent two geometric observables: the superluminal speed $\beta_{\rm obs}$ in units of c and the Doppler factor δ deduced from X-ray properties of the source. The region $\beta_{\rm obs} > 1$ constraints the values of (θ, γ) for which the speed is superluminal.

between the events B1 and B2 is simply $t_1 - t_2$. However, the time interval between the arrival at Earth of radio waves from the two events is much less than $t_1 - t_2$, because the blob moves almost as fast as the radio waves it emitted at an earlier time. This is the essence of the phenomenon—if the timescale is compressed, than the apparent speed is increased: the apparent speed is an over-estimate of the true speed.

This compression can be easily quantified. The projected separation of B1 and B2, as deduced from the images, is $v(t_1 - t_2)\sin\theta$. When the blob reaches $B2$, the radio signals from $B1$ are closer to earth by an amount $c(t_1 - t_2) - v(t_1 - t_2)\cos\theta$. Hence the time interval between the VLBI images is $(t_1 - t_2) - (v/c)(t_1 - t_2)\cos\theta$. The apparent speed $v_{\rm obs}$ is simply the projected separation divided by the time difference between the arrival times of signals from $B1$ and $B2$. Hence

$$v_{\rm obs} = \beta_{\rm obs} c = v \sin\theta / [1 - (v/c)\cos\theta].$$

This formula for the apparent speed applies to any angle θ and any jet speed $v = \beta c$ where $\beta < 1$. The regime of superluminal motion corresponds to small θ and v approaching c. Hence $v_{\rm obs} > c$ is not in conflict with special relativity.

Other explanations of superluminal motion

Many explanations of superluminal motion have been proposed. The above geometric explanation, based on Einstein's SPECIAL RELATIVITY, is straightforward and by far the most widely accepted. Alternative explanations of superluminal motion are possible. The most direct is that special relativity is incorrect—in other words, very high speeds are acceptable. However, this explanation would require a major re-write of the laws of physics as currently understood, because special relativity has been experimentally verified in a wide variety of situations. Furthermore, models allowing speeds in excess of c are logically inconsistent with the simple geometric model below.

An alternative explanation which is possible, in principle, is that the distance to the superluminal source has been overestimated. To compute a speed from a measured PROPER MOTION across the sky, one requires the distance to the source. Distances to AGN are computed using their REDSHIFT and the cosmological interpretation of the HUBBLE CONSTANT. Eliminating superluminal motion in AGN would require either a non-cosmological redshift (i.e. that the redshift is not a measure of the source distance) or increasing the Hubble constant by a factor of 10. While these possibilities do not violate any known physics directly, they are inconsistent with the body of astronomical data on scales from parsecs to megaparsecs.

The 'Christmas tree' model is more plausible. In this model superluminal components in a radio source are represented by randomly flashing lights. This allows arbitrarily large speeds, because there is no *causal* relation between successive images. If this explanation is correct, then most superluminal sources would show random variations between successive images, with no preference for expansions over contractions. In poorly sampled time sequences, this may appear to be the case. However, in

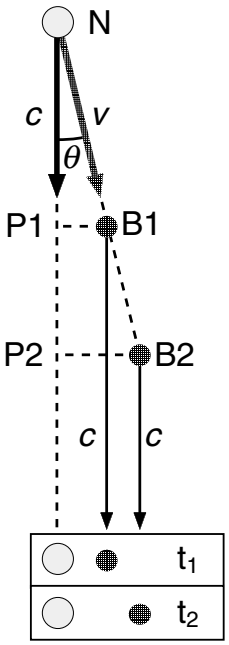

Figure 2. Geometric explanation of superluminal motion. At a time t_0, a quasar nucleus (N) ejects a blob of plasma (shaded dot) traveling at speed $v = \beta c$ ($\beta < 1$) along a 'jet' at an angle θ to the line of sight to the observer (shaded arrow). Both the nucleus and the blob emit radio waves (black arrows), which result in the schematic radio images shown at the bottom, corresponding to the blob passing points B1 and B2 in the jet. In the observer's frame, the time interval between events B1 and B2 is greatly compressed, resulting in an apparent jet speed which is an overestimate of the true speed (see text).

cases when the images are of good quality, and the time sampling is adequate, the motions are highly organized, with expansions almost invariably favored. In rare cases, GRAVITATIONAL LENSING, due to chance alignment of a massive object along the line of sight, can cause distortions in quasar images resulting in superluminal motion. Again, contractions should be as common as expansions, but this explanation remains possible in a handful of cases.

Another class of non-causal model is termed the 'lighthouse model'. A rotating beam from the quasar illuminates stationary clouds that reflect the radio waves to Earth. Again, because there is no causal relation between the emitting regions, very high apparent speeds are possible in certain geometric orientations. This model yields organized motions, such as are seen, but again should show no preference for expansions over contractions. A similar non-causal superluminal model uses 'light echos'. A flare propagates out from the nucleus, illuminating nearby material, which emits radiation toward the observer. Light echos have been convincingly seen in a few active galaxies, in the evolution of the optical spectra from the nucleus. Images of a light echo source should show a maximum speed of $2c$, which is inconsistent with the bulk of the available active galaxy data (Vermeulen and Cohen 1994). However, the ring around supernova SN1987A and the varying intensity of its emission are explained well by this model.

Statistics of superluminal motion

Observations of superluminal sources are subject to strong selection effects, because the brightness of a source increases if it is moving toward the Earth (resulting in Doppler boosting). The receding jet, or counter-jet, is often dimmed by this effect to the point of undetectability. Doppler boosting is dependent on a geometric combination of θ and γ, just like superluminal motion. The boost, relative to a stationary emitter is $\delta^{3+\alpha}$ where α is the power-law spectral index of the emission defined by $S \propto \nu^{\alpha}$, where S is the flux density, and ν is the observing frequency. δ is the Doppler factor (or blueshift factor), and is given by

$$\delta = \gamma^{-1}(1 - \beta\cos\theta)^{-1}$$

where the jet Lorentz factor $\gamma = (1 - \beta^2)^{-1/2}$.

δ and $\beta_{\rm obs}$ are shown in figure 3, as functions of θ and γ. This plot is a tool for deriving the important Lorentz factor γ and other geometric quantities, since they can be derived from measurements of δ and $\beta_{\rm obs}$. For instance, a measured jet to counter-jet brightness ratio excludes a circular region, centered on the origin, in this parameter space.

Many observational consequences result from this simple model, and a number are being actively studied. Relativistic beaming ensures that most of the quasars well studied with VLBI are those that are beamed almost at the Earth, since these are the brightest and easiest to observe. However, only a small fraction of the parent population can be directed toward Earth, if the true orientations are random. The identification of a parent population, or populations, of objects for the superluminal sources is a topic of much current research. Are relativistic motions (β approaching 1) ubiquitous in quasars? The answer may be yes, but it depends on how extreme the selection effects are in real samples. Does a characteristic (physical) speed (i.e. Lorentz factor γ) for quasars exist? If so, then that speed can be used to measure distances out to large redshifts. The superluminal phenomenon is rare in quasars as a whole, because most are weak radio sources. Because superluminal motion involves the redshift, it may be used as a tool to study the COSMOLOGICAL EVOLUTION of the universe. In a comprehensive statistical study of a sample of 66 extragalactic sources with measured proper motions, Vermeulen and Cohen (1994) concluded that a single Lorentz factor is inconsistent with current observations.

Jet physics

Superluminal motion is one of the phenomena encountered when studying the kinematics of jets. Many extragalactic RADIO SOURCES, including the radio-loud quasars, show essentially two-dimensional 'lobe' structures on

large scales, out to Mpc. Often, but not always, a visible narrow jet links an active nucleus at the center of the host galaxy with the outer lobes. Basic physical arguments that require transport of energy from the nucleus have been widely accepted since the 1970s: the diffuse ionized lobes require continuous re-supply of energy in order to emit radio waves. The jets are streams of particles with high bulk kinetic energy which provide this transport of energy and matter. The physics of jets remains a very active area of astronomical research, because of the wide range of physical processes which occur within jets and in their interactions with the 'host' galaxy medium. BLAZARS represent the most extreme examples of AGN. Almost all are strong, highly variable, radio sources, but also emit so strongly in other wavebands (including the hardest gamma rays) that they are among the most luminous objects in the universe. Jets may remain relativistic to large radii, but most are too faint to detect reliably in the radio beyond a few milliarcsec. A handful, including the famous 20 arcsec jet in quasar 3C 273, are visible in the optical.

Superluminal motion is just one of a number of observations which can help us to understand the physics of relativistic jets (see review by Marscher 1998). Doppler boosting in jets (the $\delta^{3+\alpha}$ factor described above) is the key to understanding the broad-band energy emission from active galaxies. The shape of the overall spectrum—from radio waves to gamma rays—is determined not only by the intrinsic emission from the nucleus and jet but also by Doppler boosting which results from bulk flow of emitting material. In the case of 3C 345, Unwin and Wehrle (1992) showed that the x-ray emission generated via the inverse-Compton process should exceed the actual x-ray brightness measured by x-ray satellites, unless Doppler boosting is present. Surveys have combined x-ray and VLBI data to deduce lower limits to the Doppler boosting of samples of superluminal radio sources.

Not all superluminal sources are quasars or AGN. A few objects in the MILKY WAY GALAXY also show superluminal motion. An example is GRS 1915+105, a relativistic jet source, which emits strongly in x-rays as well as in the radio (Rodriguez and Mirabel 1999). Because the object is within our Galaxy, the apparent speed of $1.25c$ is detectable in less than a day, compared with months to years for the much more distant (and powerful) AGN. Galactic superluminal sources are of particular interest because of the opportunity to study a relativistic jet 'up close'. While important differences exist, the study of these nearby 'mini blazars' may help our understanding of the most distant and powerful objects in the universe.

Supermassive Black Holes in Active Galactic Nuclei

QUASARS are among the most energetic objects in the universe. We now know that they live at the centers of galaxies and that they are the most dramatic manifestation of the more general phenomenon of ACTIVE GALACTIC NUCLEI (AGNs). These include a wide variety of exotica such as SYEFERT GALAXIES, RADIO GALAXIES and BL LACERTAE OBJECTS. Since the discovery of quasars in 1963, much effort has gone into understanding their energy source. The suite of proposed ideas has ranged from the relatively prosaic, such as bursts of star formation that make multiple supernova explosions, to the decidedly more colorful, such as supermassive stars, giant pulsars or 'spinars', and supermassive black holes (SMBHs). Over time, SMBHs have gained the widest acceptance. The key observations that led to this consensus are as follows.

Quasars have prodigious luminosities. Not uncommonly, $L \sim 10^{46}$ erg s^{-1}; this is 10 times the luminosity of the brightest galaxies. Yet they are tiny, because they vary on timescales of hours. From the beginning, the need for an extremely compact and efficient engine could hardly have been more apparent. Gravity was implicated, because collapse to a BLACK HOLE is the most efficient energy source known. The most cogent argument is due to Donald Lynden-Bell (1969). He showed that any attempt to power quasars by nuclear reactions alone is implausible. First, a lower limit to the total energy output of a quasar is the energy, $\sim 10^{61}$ erg, that is stored in its radio-emitting plasma halo. This energy weighs 10^{40} g or $10^7 M_\odot$. However, nuclear reactions produce energy with an efficiency of only $\varepsilon = 0.7\%$. Then the waste mass left behind in powering quasars would be at least $M_\bullet \simeq 10^9 M_\odot$. Lynden-Bell argued further that quasar engines are $2R \approx 10^{15}$ cm in diameter because large variations in quasar luminosities are observed on timescales as short as 10 h. However, the gravitational potential energy of $10^9 M_\odot$ compressed into a volume as small as 10 light-hours is $\sim GM_\bullet^2 < / R \gtrsim 10^{62}$ erg. As Lynden-Bell noted, 'Evidently although our aim was to produce a model based on nuclear fuel, we have ended up with a model which has produced more than enough energy by gravitational contraction. The nuclear fuel has ended as an irrelevance'. We now know that the total energy output is larger than the energy that is stored in a quasar's radio source; this strengthens the argument. Meanwhile, a caveat has appeared: the objects that vary most rapidly are now thought to contain relativistic jets that are beamed at us. This boosts the power of a possibly small part of the quasar engine and weakens the argument that the object cannot vary on timescales less than the light travel time across it. However, this phenomenon would not occur at all if relativistic motions were not involved, so SMBH-like potential wells are still implicated. These considerations suggest that quasar power derives from gravity.

The presence of deep gravitational potentials has long been inferred from the large velocity widths of the emission lines seen in optical and ultraviolet spectra of AGNs. These are typically 2000–10 000 km s^{-1}. If the large Doppler shifts arise from gravitationally bound gas, then the binding objects are both massive and compact. The obstacle to secure interpretation has always been the realization that gas is easy to push around: explosions and ejection of gas are common astrophysical phenomena. The observation that unambiguously points to relativistically deep gravitational potential wells is the detection of radio jets with plasma knots that are seen to move faster than the speed of light, c. Apparent expansion rates of (1–10)c are easily achieved if the true expansion rate approaches c and the jet is pointed almost at us.

The final pillar on which the SMBH paradigm is based is the observation that many AGN jets are well collimated and straight. Evidently AGN engines can remember ejection directions with precision for up to 10^7 yr. The natural explanation is a single rotating body that acts as a stable gyroscope. Alternative AGN engines that are made of many bodies—such as stars and supernovae—do not easily make straight jets.

A variety of other evidence also is consistent with the SMBH picture, but the above arguments were the ones that persuaded a majority of the astronomical community to take the extreme step of adopting SMBHs as the probable engine for AGN activity. In the meantime, SMBH alternatives such as single supermassive stars and spinars were shown to be dynamically unstable and hence short lived. Even if such objects can form, they are believed to collapse to SMBHs.

The above picture became the paradigm long before there was direct evidence for SMBHs. Dynamical evidence is the subject of this article and the following one (SUPERMASSIVE BLACK HOLES IN ACTIVE GALAXIES). Meanwhile, there are new kinds of observations that point directly to SMBH engines. In particular, recent observations by the Advanced Satellite for Cosmology and Astrophysics (ASCA) have provided strong evidence for relativistic motions in AGNs. The x-ray spectra of many Seyfert galaxy nuclei contain iron Kα emission lines (rest energies of 6.4–6.9 keV; see figure 1). These lines show enormous Doppler broadening—in some cases approaching 100 000 km s^{-1} or 0.3c—as well as asymmetric line profiles that are consistent with relativistic boosting and dimming in the approaching and receding parts, respectively, of SMBH accretion disks as small as a few Schwarzschild radii.

The foregoing discussion applies to the most powerful members of the AGN family, namely quasars and high-luminosity Seyfert and radio galaxies. It is less

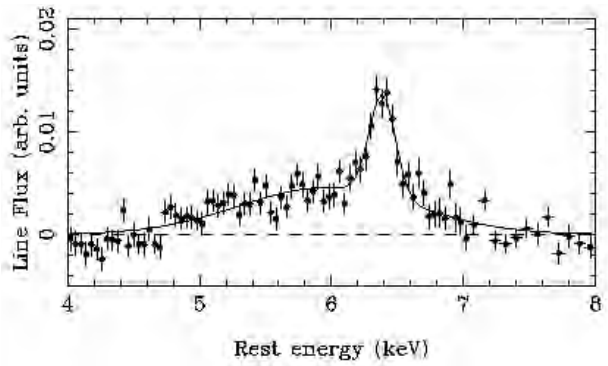

Figure 1. A composite x-ray spectrum of Seyfert nuclei taken with *ASCA* showing the relativistically broadened Fe Kα line. The solid curve is a fit to the line profile using two Gaussians, a narrow component centered at 6.4 keV and a much broader, redshifted component. (Figure adapted from Nandra K *et al* 1997 *Astrophys. J.* **477** 602.)

compelling for the more abundant low-luminosity objects, where energy requirements are less demanding and where long jets or superluminal motions are seen less frequently or less clearly. Therefore a small but vocal competing school of thought continues to argue that stellar processes alone, particularly those that occur during bursts of STAR FORMATION, can reproduce many AGN characteristics. Nonetheless, dynamical evidence suggests that SMBHs *do* lurk in some mildly active nuclei, and, as discussed in the next article, even in the majority of inactive galaxies.

Measuring AGN masses: direct methods

Very general arguments suggest that quasar engines have masses $M_\bullet \sim 10^6$–$10^9 M_\odot$. Gravitational collapse is believed to liberate energy with an efficiency of $\varepsilon \simeq 0.1$; Lynden-Bell's arguments then imply that typical remnant masses are $M_\bullet \sim 10^8 M_\odot$. Better estimates can be derived by asking what we need in order to power quasar luminosities, which range from 10^{44} to 10^{47} erg s^{-1} or $10^{11} L_\odot$ to $10^{14} L_\odot$. For $\varepsilon = 0.1$, the engine must consume 0.02–$20 M_\odot$ yr^{-1}. How much waste mass accumulates depends on how long quasars live. This is poorly known. If they live long enough to make radio jets that are collimated over several Mpc, and if their lifetimes are conservatively estimated as the light travel time along the jets, then quasars last $\gtrsim 10^7$ yr and reach masses $M_\bullet \gtrsim 10^5$–$10^8 M_\odot$. However, the most rigorous lower limit on $M_\bullet$ follows from the condition that the outward force of radiation pressure on accreting matter not overwhelm the inward gravitational attraction of the engine, a condition which, admittedly, strictly holds only if the accreting material and the radiation have spherical symmetry. This so-called Eddington limit requires that $L \leq L_E \sim (4\pi G c m_p/\sigma_T) M_\bullet = 1.3\times10^{38}\ (M_\bullet/M_\odot)$ erg s^{-1}, or

equivalently that $M_\bullet \geq 8\times10^5 (L/10^{44}\ \mathrm{erg\ s^{-1}}) M_\odot$. Here G is the gravitational constant, m_p is the mass of the proton and σ_T is the Thompson cross section for electron scattering. We conclude that we are looking for SMBHs with masses $M_\bullet \sim 10^6$–$10^9 M_\odot$. Finding them has become one of the 'Holy Grails' of astronomy because of the importance of confirming or disproving the AGN paradigm.

AGNs provide the impetus to look for SMBHs, but ACTIVE GALAXIES are the most challenging hunting ground. Stellar dynamical searches first found central dark objects in inactive galaxies (see SUPERMASSIVE BLACK HOLES IN INACTIVE GALAXIES), but they cannot be applied in very active galaxies, because the nonthermal nucleus outshines the star light. We can estimate masses using the kinematics of gas, but only if it is unperturbed by nongravitational forces. Fortunately, this complication can be ruled out *a posteriori* if we observe that the gas is in Keplerian rotation around the center, i.e. if its rotation velocity as a function of radius is $V(r):r^{-1/2}$. We can also stack the cards in our favor by targeting galaxies that are only weakly active and that appear to show gas disks in images taken through narrow bandpasses centered on prominent emission lines.

Kinematics of optical emission lines

High-resolution optical images taken with ground-based telescopes and especially with the Hubble Space Telescope (HST) show that many giant ELLIPTICAL GALAXIES contain nuclear disks of dust and ionized gas. The most famous case is M87 (figure 2(*a*)). The disk measures ~150 pc across, and its rotation axis is closely aligned with the optical and radio jet. This is in accord with the SMBH accretion picture. The disk is in Keplerian rotation figure 2(*b*)) around an object of mass $M_\bullet \simeq 3\times10^9 M_\odot$. Furthermore, this object is dark: the measured mass-to-light ratio exceeds 100 in solar units, and this is much larger than that of any known population of stars. Moreover, the dark mass must be very compact: the velocity field limits its radial extent to be less than 5 pc. Therefore its density exceeds $10^7 M_\odot$ pc^{-3}. Another illustration of this technique is given in figure 3. M84, also a denizen of the Virgo cluster of galaxies, is a twin of M87 in size, and it, too, harbors an inclined nuclear gas disk (diameter ~80 pc), whose rotation about the center betrays an invisible mass of $M_\bullet \simeq 2\times10^9 M_\odot$. Other cases are reported (NGC 4261, NGC 6251, NGC 7052), and searches for more are in progress.

Kinematics of radio masers

A related approach exploits the few cases where 22 GHz microwave maser emission from water molecules has been found in edge-on nuclear disks of gas. Particularly strong 'megamasers' allow radio astronomers to use interferometry to map the velocity field with exquisite angular resolution. In the most dramatic application of this method, the Very Long Baseline Array was used to achieve resolution 0´´.0006—100 times better than that delivered by HST—in observations of the Seyfert galaxy NGC 4258. This is only 6 Mpc away, so the linear resolution was a remarkable 0.017 pc. The masers trace out a slightly warped annulus with an inner radius of 0.13 pc, an outer radius of 0.26 pc and a thickness of <0.003 pc (figure 4, left). The masers with nearly zero velocity with respect to the galaxy are on the near side of the disk along the line of sight to the center, while the features with high negative (approaching) and positive (receding) velocities come from the disk on either side of the center. High velocities imply that $3.6\times10^7 M_\odot$ of binding matter resides interior to r=0.13 pc. What is most compelling about NGC 4258 is the observation that the rotation curve is so precisely Keplerian (figure 4, right). From this result, one can show that the radius of the mass distribution must be $r \lesssim 0.012$ pc. If the central mass were not an SMBH, its density would be extraordinarily high, $\rho; > 5\times10^{12} M_\odot$ pc^{-3}. This is comparable with the density of the dark mass at the center of our Galaxy (see SUPERMASSIVE BLACK HOLES IN ACTIVE GALAXIES). Under these extreme conditions, one can show that a cluster of stellar

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

remnants (white dwarf stars, neutron stars and stellar-size black holes) or substellar objects (planets and brown dwarfs) is short lived. Astrophysically, these are the most plausible alternatives to an SMBH. Therefore the dynamical case for an SMBH is stronger in NGC 4258 and in our Galaxy than in any other object.

Measuring AGN masses: indirect methods

Direct dynamical measurements are impractical for more luminous and more distant AGNs. The tremendous glare from the nucleus outshines the circumnuclear emission from stars, and the violent conditions near the center are likely to subject the gas to nongravitational forces. Indirect methods of estimating central masses have been devised to provide a reality check for these more difficult objects.

Fitting the spectra of accretion disks

As material falls toward a black hole, it is believed to settle into an ACCRETION DISK in which angular momentum is dissipated by viscosity. From the virial theorem, half of the gravitational potential energy U is radiated. Therefore the luminosity is

$$L = \frac{1}{2}\frac{\mathrm{d}U}{\mathrm{d}t} = \frac{1}{2}\frac{GM_\bullet \dot{M}_\bullet}{r}.$$

At sufficiently high accretion rates $\dot{M}_\bullet$, the gas is optically thick, and the disk radiates as a thermal blackbody:

$$L = 2\pi r^2 \sigma T^4.$$

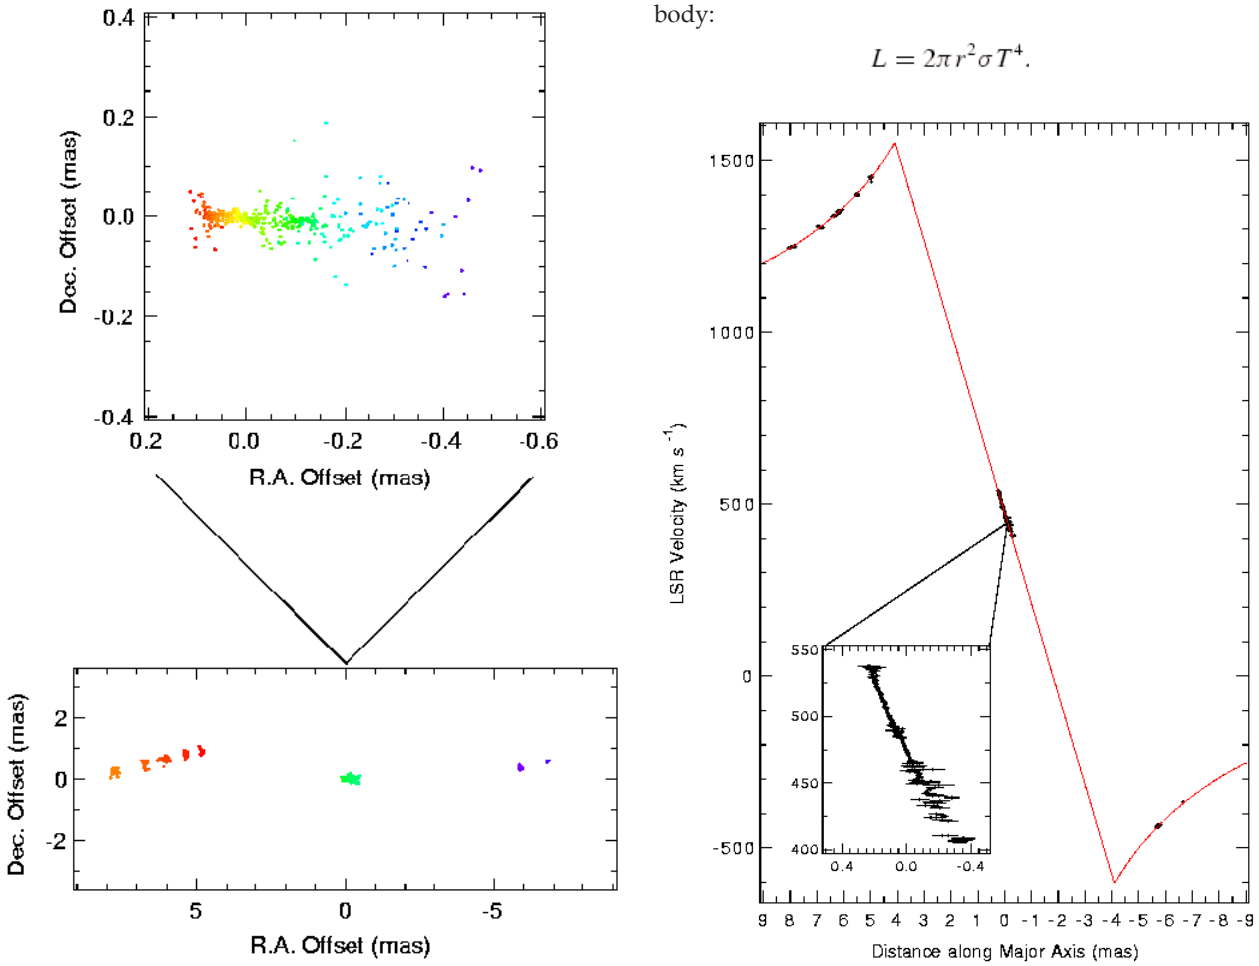

Figure 4. (Left) Spatial distribution of the water masers in NGC 4258, with redshifted velocities to the left and blueshifted velocities to the right. The maser spots are distributed in a thin, warped annulus that is only 4° from edge on. For an adopted distance of 6.4 Mpc, 1 mas=0.031 pc. The top panel shows an expanded view of the emission near the systemic velocity of the galaxy. (Right) Light-of-sight velocity as a function of distance along the major axis of the annulus. The high-velocity features are accurately fitted by a Keplerian model, overplotted as a continuous line. The emission near the systemic velocity, magnified in the inset, lies at nearly constant radius in the front part of the disk along the line of sight to the center. The linear velocity gradient results from the change in projection of the rotation velocity. (Figure adapted from Miyoshi M *et al* 1995 *Nature* **373** 127.)

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998

Here $2\pi r^2$ is the surface area of the disk and σ is the Stefan–Boltzmann constant. The effective temperature of the disk as a function of radius r is therefore

$$T(r) \simeq \left(\frac{GM_\bullet \dot{M}_\bullet}{4\pi\sigma r^3}\right)^{1/4}.$$

Parameterizing the above result in terms of the Eddington accretion rate, $\dot{M}_E \sim L_E/\varepsilon c^2 = 2.2(\varepsilon/0.1)^{-1}(M_\bullet/10^8 M_\odot)\ M_\odot\ \mathrm{yr}^{-1}$, and the Schwarzschild radius, $R_S \sim 2GM_\bullet/c^2 = 2.95\times10^{13}(M_\bullet/10^8 M_\odot)$ cm, gives

$$T(r) = 6\times10^5\ \mathrm{K}\left(\frac{\dot{M}_\bullet}{\dot{M}_E}\right)^{1/4}\left(\frac{M_\bullet}{10^8 M_\odot}\right)^{-1/4}\left(\frac{r}{R_S}\right)^{-3/4}.$$

In other words, the peak of the blackbody spectrum occurs at a frequency of $\nu_{max} = 2.8kT/h \simeq 4\times10^{16}$ Hz, where k is Boltzmann's constant and h is Planck's constant. This peak is near 100 å or 0.1 keV. In fact, the spectra of many AGNs show a broad emission excess at extreme ultraviolet or soft x-ray wavelengths. This 'big blue bump' has often been identified with the thermal emission from the accretion disk. A fit to the luminosity and the central frequency of the big blue bump gives $M_\bullet$ and $\dot{M}_\bullet$ but not each separately. Corrections for disk inclination and relativistic effects further complicate the analysis. This method is therefore model dependent and provides only approximate masses. Typical values for quasars are $M_\bullet \simeq (10^8$–$10^{9.5})M_\odot$ and $\dot{M}_\bullet \simeq (0.1$–$1)\,\dot{M}_E$. Seyfert nuclei appear to have lower masses, $M_\bullet \simeq (10^{7.5}$–$10^{8.5})M_\odot$, and lower accretion rates, $\dot{M}_\bullet \simeq (0.01$–$0.5)\dot{M}_E$.

Virial masses from optical variability

Surrounding the center at a distance of 0.01–1 pc from the black hole lies the 'broad-line region' (BLR). This is a compact, dense and highly turbulent swarm of gas clouds or filaments. The clouds are illuminated by the AGN's photoionizing continuum radiation and reprocess it into emission lines that are broadened to velocities of several thousand km s^{-1} by the strong gravitational field of the black hole. Then

$$M_\bullet = \eta\frac{v^2 r_{BLR}}{G}$$

where $\eta \simeq 1$–3 depends on the kinematic model adopted, v is the velocity dispersion of the gas as reflected in the widths of the emission lines and r_{BLR} is the radius of the BLR. The latter can be estimated by 'reverberation mapping', as follows. The photoionizing continuum of an AGN typically varies on timescales of days to months. In response, the emission lines vary also, but with a time delay that corresponds to the light travel time between the continuum source and the line-emitting gas. By monitoring the variations in the continuum and the emission lines in an individual object, reverberation mapping provides information on the size of the BLR. These studies also support the assumption that the line widths come predominantly from bound orbital motions. Applying equation (5) suggests that Seyfert nuclei are powered by black holes with masses $M_\bullet \sim (10^7$–$10^8)M_\odot$, while quasar engines are more massive, with $M_\bullet \sim (10^8$–$10^9)M_\odot$. Since quasars also live in more massive host galaxies, this supports the emerging correlation (see the following article) between SMBH mass and the mass of the elliptical-galaxy-like part of the host galaxy.

X-ray variability

AGNs vary most conspicuously in hard x-rays (2–10 keV). One might hope to use the variability timescale to constrain the size of the x-ray-emitting region and hence to estimate the central mass. However, no simple pattern of variability emerges, and defining a meaningful timescale is ambiguous. One approach uses the 'fastest doubling time', Δt, to establish a maximum source size $R \simeq c\,\Delta t$. High-energy photons presumably come from the hot, inner regions of the accretion disk or in an overlying hot corona. For example, if $R \simeq 5R_S$, as deduced in some models, we obtain an upper limit to the mass, $M_\bullet \lesssim (c^3/10G)\,\Delta t \sim 10^4\,\Delta t\,M_\odot$ (Δt in s). Masses estimated in this way are generally consistent with those obtained from other virial arguments, but they are considerably less robust because of uncertainties in associating the variability timescale with a source size. For example, the x-ray intensity variations could originate from localized 'hotspots' in the accretion flow.

X-ray reverberation mapping may in the future be a more powerful tool. The iron Kα line is widely believed to be produced by reprocessing of the hard x-ray continuum by the accretion disk. The strikingly large width and skewness of the line profiles (figure 1), now routinely detected with ASCA, reflect the plasma bulk motion within 10–100 gravitational radii of the center. The temporal response of the line strength and line profile depends on a number of factors that, in principle, can be modeled theoretically; these include the geometry of the x-ray source, the structure of the disk, and the assumed (Schwarzschild or Kerr) metric of the black hole. Time-resolved X-ray spectroscopy should become feasible with the X-ray Multi-Mirror Mission (XMM) in the near future. We can then look forward to constraints on both the masses and the spins of SMBHs.

Summary and prospects

he black hole model for AGN activity has been successful and popular for over three decades. It has withstood the test of time not—at least until recently—because the empirical evidence for SMBHs has been overwhelming but because the alternatives are so implausible. Now progress has advanced on several fronts. The refurbished

HST has greatly strengthened the evidence, already growing from ground-based observations, that supermassive dark objects live at the centers of most galaxies. The pace of discoveries is accelerating. The dark objects have exactly the range of masses that we need to explain AGN engines, but we have had no proof that they must be black holes. Then radio interferometry revealed the spectacular maser disk in NGC 4258. For its rotation curve to be as accurately Keplerian as we observe, the central mass must be confined to an astonishingly tiny volume. The inferred density of the central object is so high that astrophysically plausible alternatives can be excluded; an SMBH is the best explanation. The same conclusion has been reached for the SMBH candidate at the center of our Galaxy. This is a major conceptual breakthrough.

In addition, ASCA has demonstrated that many AGNs show iron emission lines with relativistically broadened profiles. This is arguably the best evidence for the strong gravitational field of a black hole. One of the most interesting prospects for the future is time-resolved x-ray spectroscopy, because hot gas probes closest to an accreting black hole.

Finally, the AGN paradigm can be turned inside out to give what may prove to be the most direct argument for black holes. SMBHs were 'invented' to explain nuclear activity in galaxies. In recent years, an ironic situation has developed: some SMBH candidates are too inactive for the amount of matter that we believe they are accreting. The same is true of some stellar-mass black hole candidates that accrete gas from evolving companion stars. A number of researchers recently have developed a theory of 'advection-dominated accretion' in which the accretion disk cannot radiate most of its energy before it reaches R_S either because it is optically thick or because it is too thin to cool. Unless most of the inflowing material ultimately escapes through an outflow, a possibility being explored, the only way to make the accretion energy disappear is to ensure that the accreting body does not have a hard surface. That is, the inactivity of well-fed nuclear engines may be evidence that they have event horizons. Finding event horizons would be definitive proof that AGN engines are black holes.

Bibliography

Initial debate concerning the physical nature of quasars is summarized in

Burbidge G and Burbidge E M 1967 *Quasi-Stellar Objects* (San Francisco: Freeman)

The three key historical papers that originated the SMBH hypothesis are

Lynden-Bell D 1969 *Nature* **223** 690
Salpeter E E 1964 *Astrophys. J.* **140** 796
Zel'dovich Ya B and Novikov I D 1964 *Sov. Phys. Dokl.* **158** 811

The argument for 'gravity power' was further developed in

Lynden-Bell D 1978 *Phys. Scripta* **17** 185

Textbook style discussions of AGN physics can be found in

Courvoisier T J-L and Mayor M 1990 *Active Galactic Nuclei* (Saas-Fee Course 20) (Berlin: Springer)
Peterson B M 1997 *An Introduction to Active Galactic Nuclei* (Cambridge: Cambridge University Press)

The SMBH paradigm is covered at a more technical level in the following review articles:

Begelman M C, Blandford R D and Rees M J 1984 *Rev. Mod. Phys.* **56** 255
Blandford R D 1990 *Active Galactic Nuclei (Saas-Fee Course 20)* ed T J-L Courvoisier and M Mayor (Berlin: Springer) p 161
Rees M J 1984 *Annu. Rev. Astron. Astrophys.* **22** 471

The search for SMBHs is reviewed in

Kormendy J and Richstone D 1995 *Annu. Rev. Astron. Astrophys.* **33** 581

Supermassive Black Holes in Inactive Galaxies

Several billion years after the big bang, the universe went through a 'quasar era' when high-energy ACTIVE GALACTIC NUCLEI (AGNs) were more than 10 000 times as numerous as they are now. QUASARS must then have been standard equipment in most large galaxies. Since that time, AGNs have been dying out. Now quasars are exceedingly rare, and even medium-luminosity AGNs such as SEYFERT GALAXIES are uncommon. The only activity that still occurs in many galaxies is weak. A paradigm for what powers this activity is well established through the observations and theoretical arguments that are outlined in the article SUPERMASSIVE BLACK HOLES IN AGN. AGN engines are believed to be supermassive black holes (BHs) that accrete gas and stars and so transform gravitational potential energy into radiation. Expected BH masses are $M_\bullet \sim 10^6$–$10^{9.5} M_\odot$. A wide array of phenomena can be understood within this picture. However, the subject has had an outstanding problem: there was no dynamical evidence that BHs exist. The search for BHs has therefore become one of the hottest topics in extragalactic astronomy.

Since most quasars have switched off, dim or dead engines—starving BHs—should be hiding in many nearby galaxies. This means that the BH search need not be confined to the ACTIVE GALAXIES that motivated it. In fact, definitive conclusions are much more likely if we observe objects in which we do not, as Alan Dressler has said, 'have a searchlight in our eyes'. Also, it was necessary to start with the nearest galaxies, because only then could we see close enough to the center so that the BH dominates the dynamics. Since AGNs are rare, nearby galaxies are not particularly active. For these reasons, it is no surprise that the search first succeeded in nearby, inactive galaxies.

This article discusses stellar dynamical evidence for BHs in inactive and weakly active galaxies. Stellar motions are a particularly reliable way to measure masses, because stars cannot be pushed around by nongravitational forces. The price is extra complication in the analysis: the dynamics are collisionless, so random velocities can be different in different directions. This is impossible in a collisional gas. As we shall see, much effort has gone into making sure that unrecognized velocity anisotropy does not lead to systematic errors in mass measurements.

Dynamical evidence for central dark objects has been published for 17 galaxies. With the Hubble Space Telescope (HST) pursuing the search, the number of detections is growing rapidly. Already we can ask demographic questions. Two main results have emerged. First, the numbers and masses of central dark objects are broadly consistent with predictions based on quasar energetics. Second, the central dark mass correlates with the mass of the ELLIPTICAL-GALAXY-like 'bulge' component of galaxies. What is less secure is the conclusion that the central dark objects must be BHs and not (for example) dense clusters of brown dwarf stars or stellar remnants. Rigorous arguments against such alternatives are available for only two galaxies. Nevertheless, these two objects and the evidence for dark masses at the centers of almost all galaxies that have been observed are taken as strong evidence that the AGN paradigm is essentially correct.

Dead quasar engines in nearby galaxies

The qualitative discussion of the previous section can be turned into a quantitative estimate for $M_\bullet$ as follows. The quasar population produces an integrated comoving energy density of

$$u = \int_0^\infty \int_0^\infty \Phi(L, z) L \, \mathrm{d}L \frac{\mathrm{d}t}{\mathrm{d}z} \mathrm{d}z = 1.3 \times 10^{-15} \ \mathrm{erg\ cm^{-3}}$$

where $\Phi(L,z)$ is the comoving density of quasars of luminosity L at redshift z and t is cosmic time. For a radiative energy conversion efficiency of ϵ, the equivalent present-day mass density is $\rho_u = u/\epsilon c^2 = 2.2 \times 10^4 \ \epsilon^{-1} \ M_\odot \ \mathrm{Mpc}^{-3}$. Comparison of ρ_u with the overall galaxy luminosity density, $\rho_g \simeq 1.4 \times 10^8 h L_\odot \ \mathrm{Mpc}^{-3}$, where the Hubble constant is $H_0 = 100h$ km s^{-1} Mpc^{-1}, implies that a typical nearby bright galaxy (luminosity $L^* \simeq 10^{10} h^{-2} L_\odot$) should contain a dead quasar of mass $M_\bullet \sim 1.6 \times 10^6 \epsilon^{-1} h^{-3} M_\odot$. Accretion onto a BH is expected to produce energy with an efficiency of $\epsilon \sim 0.1$, and the best estimate of h is $\simeq 0.71 \pm 0.06$. Therefore the typical BH should have a mass of $\sim 10^{7.7} M_\odot$. BHs in dwarf ellipticals should have masses of $\sim 10^6 M_\odot$.

In fact, the brightest quasars must have had much higher masses. A BH cannot accrete arbitrarily large amounts of mass to produce arbitrarily high luminosities. For a given $M_\bullet$, there is a maximum accretion rate above which the radiation pressure from the resulting high luminosity blows away the accreting matter. This 'Eddington limit' is discussed in SUPERMASSIVE BLACK HOLES IN ACTIVE GALACTIC NUCLEI. Eddington luminosities of $L \sim 10^{47}$ erg s^{-1} $\sim 10^{14} L_\odot$ require BHs of mass $M_\bullet \gtrsim 10^9 M_\odot$. These arguments define the parameter range of interest: $M_\bullet \sim 10^6$–$10^{9.5} M_\odot$. The highest-mass BHs are likely to be rare, but low-mass objects should be ubiquitous. Are they?

Stellar dynamical searches for central dark objects

The answer appears to be 'yes'. The majority of detections on which this conclusion is based are stellar

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

dynamical. However, finding BHs is not equally easy in all galaxies. This results in important selection effects that need to be understood for demographic studies. Therefore we begin with a discussion of techniques. We then give three examples that highlight important aspects of the search. NGC 3115 is a particularly clean detection that illustrates the historical development of the search. M31 is one of the nearest galaxies and contains a new astrophysical phenomenon connected with BHs. Finally, the strongest case that the central mass is a BH and not a dark cluster of stars or stellar remnants is the one in our own Galaxy.

Stellar dynamical mass measurement

Dynamical mass measurement is conceptually simple. If random motions are small, as they are in a gas, then the mass $M(r)$ within radius r is $M(r) = V^2 r/G$. Here V is the rotation velocity and G is the gravitational constant. In stellar systems, some of the dynamical support comes from random motions, so $M(r)$ depends also on the velocity dispersion σ. The measurement technique is best described in the idealized case of spherical symmetry and a velocity ellipsoid that everywhere points at the center. Then the first velocity moment of the collisionless Boltzmann equation gives

$$M(r) = \frac{V^2 r}{G} + \frac{\sigma_r^2 r}{G}\left[- \frac{\mathrm{d}\ln \nu}{\mathrm{d}\ln r} - \frac{\mathrm{d}\ln \sigma_r^2}{\mathrm{d}\ln r} - \left(1 - \frac{\sigma_\theta^2}{\sigma_r^2}\right) - \left(1 - \frac{\sigma_\phi^2}{\sigma_r^2}\right)\right].$$

Here σ_r, σ_θ and σ_ϕ are the radial and azimuthal components of the velocity dispersion. The density ν is not the total mass density ρ; it is the density of the luminous tracer population whose kinematics we measure. We never see ρ, because the stars that contribute most of the light contribute almost none of the mass. Therefore we assume that $\nu(r) \propto$ volume brightness. All quantities in equation (2) are unprojected. We observe brightnesses and velocities after projection and blurring by a point-spread function (PSF). Information is lost in both processes. Several techniques have been developed to derive unprojected quantities that agree with the observations after projection and PSF convolution. From these, we derive the mass distribution $M(r)$ and compare it with the light distribution $L(r)$. If $M/L(r)$ rises rapidly as $r \to 0$, then we have found a central dark object.

There is one tricky problem with this analysis, and it follows directly from equation (2). Rotation and random motions contribute similarly to $M(r)$, but the $\sigma^2 r/G$ term is multiplied by a factor that depends on the velocity anisotropy and that can be less than 1. GALAXY FORMATION can easily produce a radial velocity dispersion σ_r that is larger than the azimuthal components σ_θ and σ_ϕ. Then the third and fourth terms inside the brackets in equation (2) are negative; they can be as small as –1 each. In fact, they can largely cancel the first two terms, because the second term cannot be larger than +1, and the first is $\simeq 1$ in many galaxies. This explains why *ad hoc* anisotropic models have been so successful in explaining the kinematics of giant ellipticals without BHs. However, how anisotropic are the galaxies?

Much effort has gone into finding the answer. The most powerful technique is to construct self-consistent dynamical models in which the density distribution is the linear combination $\rho = \sigma N_i \rho_i$ of the density distributions ρ_i of the individual orbits that are allowed by the gravitational potential. First the potential is estimated from the light distribution. Orbits of various energies and angular momenta are then calculated to construct a library of time-averaged density distributions ρ_i. Finally, orbit occupation numbers N_i are derived so that the projected and PSF-convolved model agrees with the observed kinematics. Some authors also maximize $\sigma N_I \ln N_i$, which is analogous to an entropy. These procedures allow the stellar distribution function to be as anisotropic as it likes in order (e.g.) to try to explain the observations without a BH. In the end, such models show that real galaxies are not extremely anisotropic. That is, they do not take advantage of all the degrees of freedom that the physics would allow. However, this is not something that one could take for granted. Because the degree of anisotropy depends on galaxy luminosity, almost all BH detections in bulges and low-luminosity ellipticals (which are nearly isotropic) are based on STELLAR DYNAMICS, and almost all BH detections in giant ellipticals (which are more anisotropic) are based on gas dynamics.

NGC 3115: $M_\bullet \simeq 10^{9.0\pm0.3} M_\odot$

One of the best stellar-dynamical BH cases is the prototypical S0 galaxy NGC 3115 (figure 1). It is especially suitable for the BH search because it is very symmetrical and almost exactly edge-on. NGC 3115 provides a good illustration of how the BH search makes progress. Unlike some discoveries, finding a supermassive BH is rarely a unique event. Rather, an initial dynamical case for a central dark object becomes stronger as observations improve. Eventually, the case becomes definitive. This has happened in NGC 3115 through the study of the central STAR CLUSTER—a tiny, dense cusp of stars like those expected around a BH (figure 1). Later, still better observations may accomplish the next step, which is to strengthen astrophysical constraints enough so that all plausible BH alternatives (clusters of dark stars) are eliminated. This has happened for our Galaxy (see below) but not yet for NGC 3115.

The kinematics of NGC 3115 show the signature of a central dark object (figure 2). The original detection was based on the crosses. Already at resolution

Figure 1. HST WFPC2 images of NGC 3115. The left panel shows a color image made from 1050 s *V*- and *I*-band images. The right panel shows a model of the nuclear disk. The center panel shows the difference; it emphasizes the compact nuclear star cluster. Brightness is proportional to the square root of intensity. All panels are 11".6 square. (This figure is taken from Kormendy *et al* 1996 *Astrophys. J. Lett.* **459** L57.)

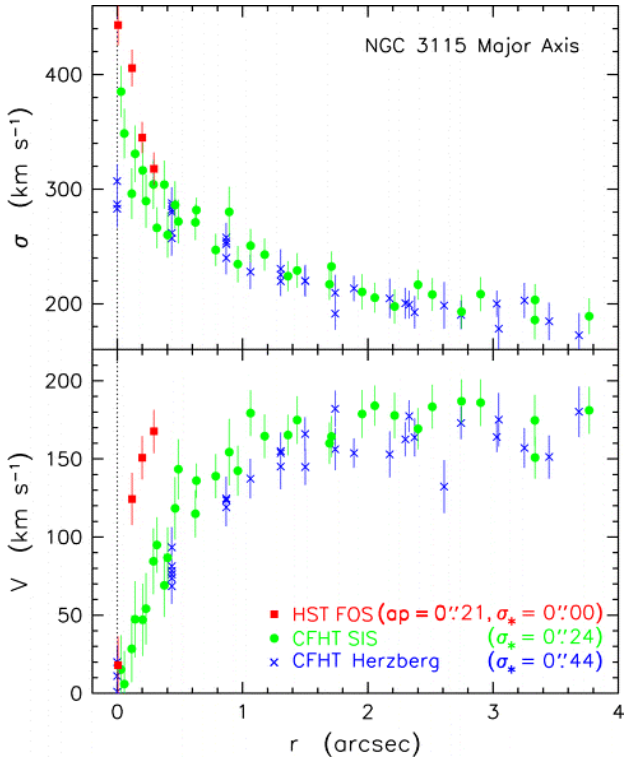

Figure 2. Rotation velocities (lower panel) and velocity dispersions (upper panel) along the major axis of NGC 3115 as observed at three different spatial resolutions. Resolution σ_* is the Gaussian dispersion radius of the PSF; in the case of the HST observations, this is negligible compared with the aperture size of 0".21. (This figure is adapted from Kormendy *et al* 1996 *Astrophys. J. Lett.* **459** L57.)

$\sigma_* = 0".44$, the central kinematic gradients are steep. The apparent central dispersion, $\sigma \simeq 300$ km s^{-1}, is much higher than normal for a galaxy of absolute magnitude $M_B = -20.0$. Therefore, isotropic dynamical models imply that NGC 3115 contains a dark mass $M_\bullet \simeq 10^{9\pm0.3} M_\odot$. Maximally anisotropic models allow smaller masses, $M_\bullet \sim 10^8 M_\odot$, but isotropy is more likely given the rapid rotation.

Since that time, two generations of improved observations have become available. The full circles in figure 2 were obtained with the Subarcsecond Imaging Spectrograph (SIS) and the Canada–France–Hawaii Telescope (CFHT). This incorporates tip-tilt optics to improve the atmospheric PSF. The observations with the HST Faint Object Spectrograph (FOS) have still higher resolution. If the BH detection is correct, then the apparent rotation and dispersion profiles should look steeper when they are observed at higher resolution. This is exactly what is seen. If the original dynamical models are 'reobserved' at the improved resolution, the ones that agree with the new data have $M_\bullet = (1–2) \times 10^9 M_\odot$.

Finally, a definitive detection is provided by the HST observations of the nuclear star cluster. Its true velocity dispersion is underestimated in figure 2, because the projected value includes bulge light from in front of and behind the center. When this light is subtracted, the velocity dispersion of the nuclear cluster proves to be $\sigma = 600\pm37$ km s^{-1}. This is the highest dispersion measured in any galactic center. The velocity of escape from the nucleus would be much smaller, $V_{esc} \simeq 352$ km s^{-1}, if it consisted only of stars. Without extra mass to bind it, the cluster would fling itself apart in $\sim 2 \times 10^4$ yr. Independent of any velocity anisotropy, the nucleus must contain an unseen object of mass $M_\bullet \simeq 10^9 M_\odot$. This is consistent with the modeling results. The dark object is more than 25 times as massive as the visible star cluster. We know of no way to make a star cluster that is so nearly dark, especially without overenriching the visible stars with heavy elements. The most plausible

explanation is a BH. This would easily have been massive enough to power a quasar.

M31: M. $\simeq 3 \times 10^7 M_\odot$

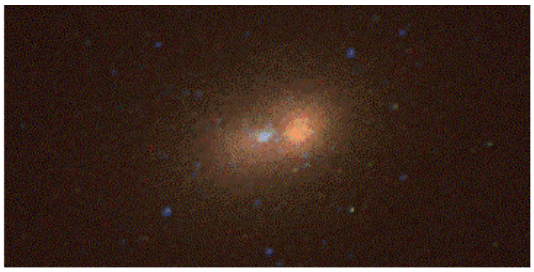
M31 is the highest-luminosity galaxy in the LOCAL GROUP. At a distance of 0.77 Mpc, it is the nearest giant galaxy outside our own. It can therefore be studied in unusual detail.

M31 contains the nearest example of a nuclear star cluster embedded in a normal bulge. When examined with HST, the nucleus appears double (figure 3). This is very surprising. At a separation of $2r = 0".49 = 1.7$ pc, a relative velocity of 200 km s^{-1} implies a circular orbit period of 50 000 yr. If the nucleus consisted of two star clusters in orbit around each other, as figure 3 might suggest, then dynamical friction would make them merge within a few orbital times. Therefore it is unlikely that the simplest possible explanation is correct: we are not observing the last stages of the digestion of an accreted companion galaxy.

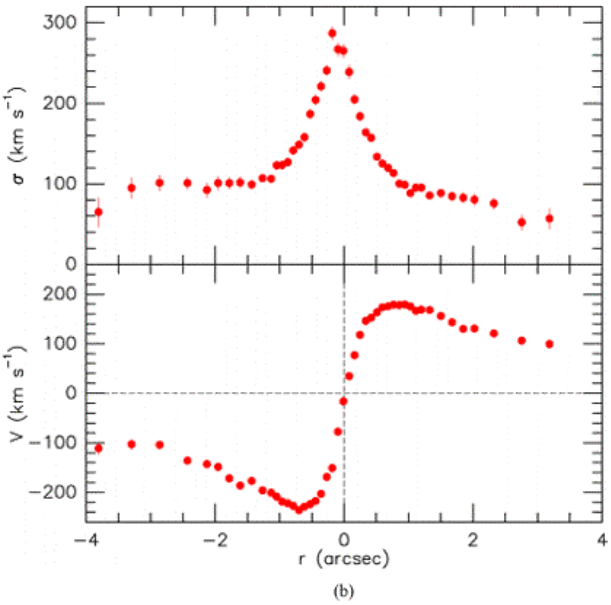
The nucleus rotates rapidly and has a steep velocity dispersion gradient (figure 3). Dynamical analysis shows that M31 contains a central dark mass $M_\bullet \simeq 3 \times 10^7 M_\odot$. The possible effects of velocity anisotropy have been checked and provide no escape. Furthermore, the asymmetry provides an almost independent check of the BH mass, as follows.

The top panel of figure 3 shows the HST image at the same scale as and registered in position with the kinematics. It shows that the dispersion peak is approximately centered on the fainter nucleus. In fact, it is centered almost exactly on a cluster of blue stars that is embedded in this nucleus. This suggests that the BH is in the blue cluster. This hypothesis can be tested by finding the center of mass of the asymmetric distribution of starlight plus a dark object in the blue cluster. The mass-to-light ratio of the stars is provided by dynamical models of the bulge at larger radii. If the galaxy is in equilibrium, then the center of mass should coincide with the center of the bulge. It does, provided that $M_\bullet \simeq 3 \times 10^7 M_\odot$. Remarkably, the same BH mass explains the kinematics and the asymmetry of the nucleus.

An explanation of the mysterious double nucleus has been proposed by Scott Tremaine. He suggests that both nuclei are part of a single eccentric disk of stars. The brighter nucleus is farther from the barycenter; it results from the lingering of stars near the apocenters of very elongated orbits. The fainter nucleus is produced by an increase in disk density toward the center. The model depends on the presence of a BH to make the potential almost Keplerian; then the alignment of orbits in the eccentric disk may be maintained by the disk's self-gravity. Tremaine's model was developed to explain the photometric and kinematic asymmetries as seen at



(a)



(b)

Figure 3. Top: HST WFPC2 color image of M31 constructed from *I*-, *V*- and 3000 Å band, PSF-deconvolved images obtained by Lauer *et al* (1998 *Astron. J.* **116** 2263). The scale is 0".0228 $pixel^{-1}$.Bottom and middle: Rotation curve $V(r)$ and velocity dispersion profile $\sigma(r)$ of the nucleus with foreground bulge light subtracted. The plots and image are printed at the same scale and are aligned in r. The symmetry point of the rotation curve and the sharp dispersion peak suggest that the BH is in the blue star cluster embedded in the left brightness peak. (This figure is adapted from Kormendy and Bender 1999 *Astrophys. J.* **522** 772.)

resolution $\sigma_* \simeq 0".5$. It is also consistent with the data in figure 3 ($\sigma_* \simeq 0".27$). The high velocity dispersion near the BH, the low dispersion in the offcenter nucleus and especially the asymmetric rotation curve are signatures of the eccentric, aligned orbits.

Most recently, spectroscopy of M31 has been obtained with the HST Faint Object Camera. This improves the spatial resolution by an additional factor of ~5. At this resolution, there is a 0".25 wide region centered on the faint nucleus in which the velocity dispersion is 440±70 km s^{-1}. This is further confirmation of the existence and location of the BH.

We do not know whether the double nucleus is the cause or an effect of the offcenter BH. However, offcenter BHs are an inevitable consequence of hierarchical structure formation and galaxy mergers (see GALAXIES: INTERACTIONS AND MERGERS). If most large galaxies contain BHs, then mergers produce binary BHs and, in three-body encounters, BH ejections with recoil. How much offset we see, and indeed whether we see two BHs or one or none at all, depends on the relative rates of mergers, dynamical friction and binary orbit decay. Offcenter BHs may have much to tell us about these and other processes. Already there is evidence in NGC 4486B for a second double nucleus containing a BH.

Our Galaxy: $M_\bullet \simeq (2.9\pm0.4) \times 10^6 M_\odot$

Our Galaxy has long been known to contain the exceedingly compact radio source Sgr A* (see SAGITTARIUS A). Interferometry gives its major- and minor-axis diameters as $63r_s$ and $<17r_s$, where $r_s = 0.06$ AU $= 8.6 \times 10^{11}$ cm is the Schwarzschild radius of a $2.9 \times 10^6 M_\odot$ BH. It is easy to be impressed by the small size. However, as an AGN, Sgr A* is feeble: its radio luminosity is only 10^{34} erg s^{-1} $\simeq 10^{0.4} L_\odot$. The infrared and high-energy luminosities are higher, but there is no compelling need for a BH on energetic grounds. To find out whether the Galaxy contains a BH, we need dynamical evidence.

Getting it has not been easy. Our Galactic disk, which we see in the sky as the Milky Way, contains enough dust to block all but $\sim 10^{-14}$ of the optical light from the Galactic center. Measurements of the region around Sgr A* had to await the development of infrared detectors. Much of the infrared radiation is in turn absorbed by the Earth's atmosphere, but there is a useful transmission window at 2.2 μm wavelength. Here the extinction toward the Galactic center is a factor of ~20. This is large but manageable. Early infrared measurements showed a rotation velocity of $V \simeq 100$ km s^{-1} and a small rise in velocity dispersion to ~120 km s^{-1} at the center. These were best fitted with a BH of mass $M_\bullet \sim 10^6 M_\odot$, but the evidence was not very strong. Since then, a series of spectacular technical advances have made it possible to probe closer and closer to the center. As a result, the strongest case for a BH in any galaxy is now our own.

Most remarkably, two independent groups led by Reinhard Genzel and Andrea Ghez have used speckle imaging to measure proper motions—the velocity components perpendicular to the line of sight—in a cluster of stars at radii $r \lesssim 0".5 \simeq 0.02$ pc from Sgr A* (figure 4). When combined with complementary measurements at larger radii, the result is that the one-dimensional velocity dispersion increases smoothly to 420±60 km s^{-1} at $r \simeq 0.01$ pc. Stars at this radius revolve around the Galactic center in a human lifetime! The mass $M(r)$ inside radius r is shown in figure 5. Outside a few pc, the mass distribution is dominated by stars, but as $r \to 0$, $M(r)$ flattens to a constant, $M_\bullet = (2.9\pm0.4) \times 10^6 M_\odot$. Velocity anisotropy is not an uncertainty; it is measured directly and found to be small. The largest dark cluster that is consistent with these data would have a central density of $4 \times 10^{12} M_\odot$ pc^{-3}. This is inconsistent with astrophysical constraints (see below). Therefore, if the dark object is not a BH, the alternative would have to be comparably exotic. It is prudent to note that rigorous proof of a BH requires that we spatially resolve relativistic velocities near the Schwarzschild radius. This is not yet feasible. However, the case for a BH in our own Galaxy is now very compelling.

BH demographics

The census of BH candidates as of January 2000 is given in table 1. The table is divided into three groups—detections based on stellar dynamics, on ionized gas dynamics, and on maser disk dynamics (top to bottom). The rate of discovery is accelerating as HST pursues the search. However, we already have candidates that span the range of predicted masses and that occur in essentially every type of galaxy that is expected to contain a BH. Host galaxies include giant AGN ellipticals (the middle group), Seyfert galaxies (NGC 1068), normal spirals with moderately active nuclei (e.g. NGC 4594 and NGC 4258), galaxies with exceedingly weak nuclear activity (our Galaxy and M31) and completely inactive galaxies (M32 and NGC 3115).

However, no complete sample has been studied at high resolution. The detections in table 1, together with low-resolution studies of larger samples of galaxies, support the hypothesis that BHs live in virtually every galaxy with a substantial bulge component. The total mass in detected remnants is consistent with predictions based on AGN energetics, within the rather large estimated errors in both quantities.

The main new demographic result is an apparent correlation between BH mass and the luminosity of the bulge part of the galaxy. This is shown in figure 6. Note that the correlation is not with the total luminosity: if the disk is included, the correlation is considerably worse. Whether the correlation is real or not is still being tested. The concern is selection effects. High-mass BHs in small galaxies are easy to see, so their scarcity is real. However, low-mass BHs can hide in giant galaxies, so the correlation may be only the upper envelope of a distribution that extends to smaller $M_\bullet$. If it is real, then the correlation implies that BH formation or feeding is connected with the mass of the high-density, elliptical-galaxy-like part of the galaxy. With the possible exception of NGC 4945 (a late-type galaxy for which the

existence and luminosity of a bulge are uncertain), BHs have been found only in the presence of a bulge. However, the limits on $M_\bullet$ in bulgeless galaxies such as M33 are still consistent with the correlation. Current searches concentrate on the question of whether small BHs—ones that are significantly below the apparent correlation—can be found or excluded.

BH mass fractions are listed in table 1 for cases in which the mass-to-light ratio of the stars has been measured. The median BH mass fraction is 0.29%. The quartiles are 0.07% and 0.9%.

Are they really BHs?

The discovery of dark objects with masses $M_\bullet \simeq (10^6$–$10^{9.5})\ M_\odot$ in galactic nuclei is secure. However, are they BHs? Proof requires measurement of relativistic velocities

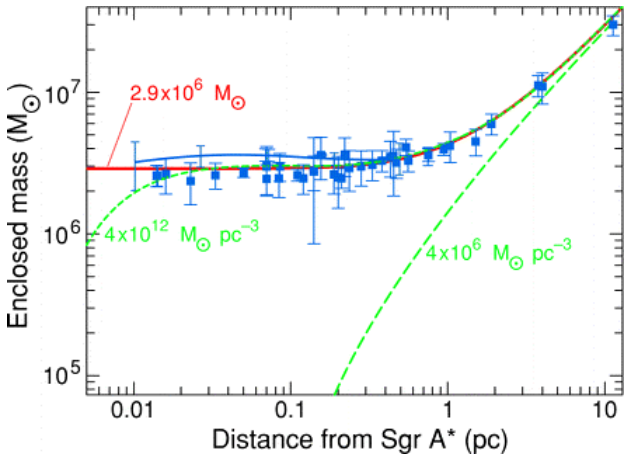

Figure 5. Mass distribution implied by proper motion and radial velocity measurements (data points and upper solid curve with representative error bars). Long dashes (right) show the mass distribution of stars if the infrared mass-to-light ratio is 2. The heavy solid curve represents the stars plus a point mass $M_\bullet = 2.9 \times 10^6 M_\odot$. Short dashes (left) provide an estimate of how non-pointlike the dark mass could be: its χ^2 value is 1 σ worse than the solid curve. This dark cluster has a core radius of 0.0042 pc and a central density of $4 \times 10^{12} M_\odot$ pc^{-3}. (This figure is updated from Genzel *et al* 1997 *Mon. Not. R. Astron. Soc.* **291** 219 and was kindly provided by R Genzel.)

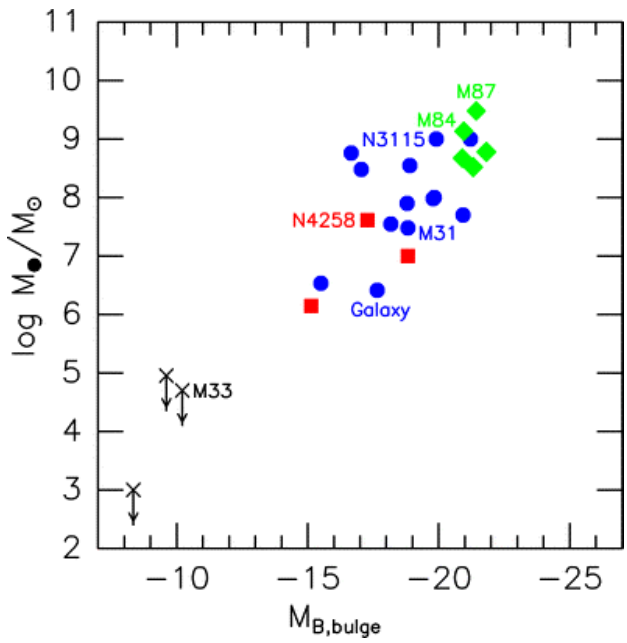

Figure 6. Correlation of BH mass with the absolute magnitude of the bulge component of the host galaxy. Since M/L varies little from bulge to bulge, this implies a correlation between BH mass and bulge mass. Filled circles indicate $M_\bullet$ measurements based on stellar dynamics, diamonds are based on ionized gas dynamics and squares are based on maser disk dynamics. It is reassuring that all three techniques are consistent with the same correlation.

velocities near the Schwarzschild radius, $r_s \simeq 2 M_\bullet/10^8 M_\odot$ AU. Even for M31, this is 8×10^{-7} arcsec. HST spectroscopic resolution is only 0".1. The conclusion that we are finding BHs is based on physical arguments that BH alternatives fail to explain the masses and high densities of galactic nuclei.

The most plausible BH alternatives are clusters of dark objects produced by ordinary STELLAR EVOLUTION. These come in two varieties, failed stars and dead stars. Failed stars have masses $m_* \lesssim 0.08 M_\odot$. They never become hot enough for the fusion reactions that power stars, i.e. the conversion of hydrogen to helium. They have a brief phase of modest brightness while they live off gravitational potential energy, but, after this, they could be used to make dark clusters. They are called brown dwarf stars, and they include planetary-mass objects. Alternatively, a dark cluster could be made of stellar remnants—WHITE DWARFS, which have typical masses of $0.6 M_\odot$; NEUTRON STARS, which typically have masses of $\sim 1.4 M_\odot$ and BHs with masses of several $M_\odot$. GALACTIC BULGES are believed to form in violent starbursts, so massive stars that turn quickly into dark remnants would be no surprise. It is not clear how one could make dark clusters with the required masses and sizes, especially not without polluting the remaining stars with more metals than we see. However, in the absence of direct proof that the dark objects in galactic nuclei are BHs, it is important to examine alternatives.

However, dynamical measurements tell us more than the mass of a potential BH. They also constrain the maximum radius inside which the dark stuff must live. Its minimum density must therefore be high, and this rules out the above BH alternatives in our Galaxy and in NGC 4258. High-mass remnants such as white dwarfs, neutron stars and stellar BHs would be relatively few in number. The dynamical evolution of star clusters is relatively well understood; in the above galaxies, a sparse cluster of stellar remnants would evaporate completely in $\lesssim 10^8$ yr. Low-mass objects such as brown dwarfs would be so numerous that collision times would be short. Stars generally merge when they collide. A dark cluster of low-mass objects would become luminous because brown dwarfs would turn into stars.

More exotic BH alternatives are not ruled out by such arguments. For example, the dark matter that makes up galactic halos and that accounts for most of the mass of the universe may in part be elementary particles that are cold enough to cluster easily. It is not out of the question that a cluster of these could explain the dark objects in galaxy centers without getting into trouble with any astrophysical constraints. So the BH case is not rigorously proved. What makes it compelling is the combination of dynamical evidence and the evidence

from AGN observations. This is discussed in the previous article.

For many years, AGN observations were decoupled from the dynamical evidence for BHs. This is no longer the case. Dynamical BH detections are routine. The search itself is no longer the main preoccupation; we can concentrate on physical questions. New technical developments such as better x-ray satellites ensure that progress on BH astrophysics will continue to accelerate.

Web update

The Chandra X-ray telescope has observed a flare of x-ray energy produced from where the lip of a supermassive black hole at the center of the Milky Way galaxy should be. The flare dimmed and brightened over a period of ten minutes, the time taken for light to travel about 150 million kilometers, meaning that it originated from an object no larger in diameter than the distance of the Earth to the Sun. This implies that the mass at the center of our Galaxy (about 2.6 million times the mass of our Sun) is crammed into that space. According to the laws of general relativity, only a black hole can be that dense.

Supernova 1987A

Supernova 1987A (SN1987A) in the LARGE MAGELLANIC CLOUD (LMC) is the brightest supernova to be observed since SN1604 (Kepler), the first to be observed in every band of the ELECTROMAGNETIC SPECTRUM and the first to be detected through its initial burst of NEUTRINOS. Although the bolometric luminosity of SN1987A today is $\approx 10^{-6}$ of its value at maximum light ($L_{max} \approx 2.5 \times 10^8 L_\odot$), it will remain bright enough to be observed for many decades in the radio, infrared, optical, UV and x-ray bands.

SN1987A is classified as a type II supernova (SNeII) (see SUPERNOVAE) by virtue of the strong hydrogen lines in its spectrum. It was atypical of SNeII in that its light curve did not reach maximum until 3 months after outburst and its maximum luminosity was about 1/10 the mean maximum luminosity of SNeII. These differences can be attributed to the fact that the star that exploded was a blue giant, unlike the progenitors of most SNeII, which we believe to be RED GIANTS.

The burst of neutrinos observed from SN1987A proved beyond doubt that its explosion followed the collapse of the core of the star, but subsequent observations have shown no evidence of the neutron star or black hole that we expect to find at the center of the debris.

The expanding gaseous debris of SN1987A cooled rapidly after the explosion. By 1000 days, its temperature was less than 2000 K throughout and the heavy elements had formed molecules and dust. With a present temperature <100 K, the inner radioactive debris is perhaps the coldest optically emitting source known to astronomers.

SN1987A is surrounded by a remarkable NEBULA of three glowing circumstellar rings (figure 1) that are evidently part of a complex system of gas that was ejected by the progenitor some 20 000 yr before it exploded and then partly ionized by the supernova flash. The approximate bipolar symmetry of this system suggests that the progenitor was once a binary system, and this interpretation may also explain why the progenitor was a blue giant rather than a red giant.

Figure 1. Circumstellar rings of SN1987A.

The outer part of the supernova debris is driving a blast wave that is beginning to strike the inner circumstellar ring at several 'hot spots' that are doubling in brightness every few months. Within the coming decade, more hotspots will appear and merge as the blast wave overtakes the entire inner ring. The ring will brighten by factors $\geqq 10^3$ at all bands of the electromagnetic spectrum, giving us unprecedented opportunities to study the physics of interstellar shocks and to view heretofore unseen circumstellar matter.

Discovery and neutrino observations

Supernova 1987A was discovered with magnitude $V \approx 5$ by Ian Shelton on February 24.23 UT, 1987. The supernova occurred in the Large Magellanic Cloud near the bright star-forming nebula 30 Doradus. Within days, several groups had obtained optical spectra and the International Ultraviolet Explorer Satellite had obtained ultraviolet spectra, showing that the outer envelope of the supernova was expanding with velocities ~0.1c (30 000 km s^{-1}). Subsequently, earlier observations were found showing that the object had magnitude $V \approx 6.5$ on February 23.443 and $V \geqq 7.5$ on February 23.39.

Soon thereafter, two independent groups reported detections of a flash of neutrinos from the direction of SN1987A that occurred on February 23.316. Electron antineutrinos produce fast positrons through the reaction $\bar{\nu}_e + p \rightarrow n + e^+$. These events are detected in large underground tanks of water through the Cherenkov light emitted by the positrons. The Kamiokande II experiment in Japan detected 12 such events and the IMB experiment in the USA detected eight events over an interval of about 12 s, during which a net background count of one event from the two detectors would be expected. The inferred energy (~3×10^{53} erg), temperature (kT~4 MeV), and decay timescale (~4 s) of the neutrino flash were in remarkably good agreement with predictions from theoretical models in which a degenerate iron core collapsed to form a NEUTRON STAR.

The initial optical display should follow the neutrino flash after a delay corresponding to the time for a blast wave to propagate through the envelope of the progenitor star. The fact that this delay was no greater than 3 h sets an upper limit $R^* \leqq 100 R_\odot$ for the radius of the progenitor star, precluding the possibility that the progenitor was a red supergiant.

Observations taken before the explosion of SN1987A showed that the progenitor star, Sk–69°202, was in fact a spectral type B2 Ia supergiant, with visual magnitude $V = 12$, bolometric luminosity $\approx 10^5 L_\odot$ and radius $R^* \approx 40 R_\odot$

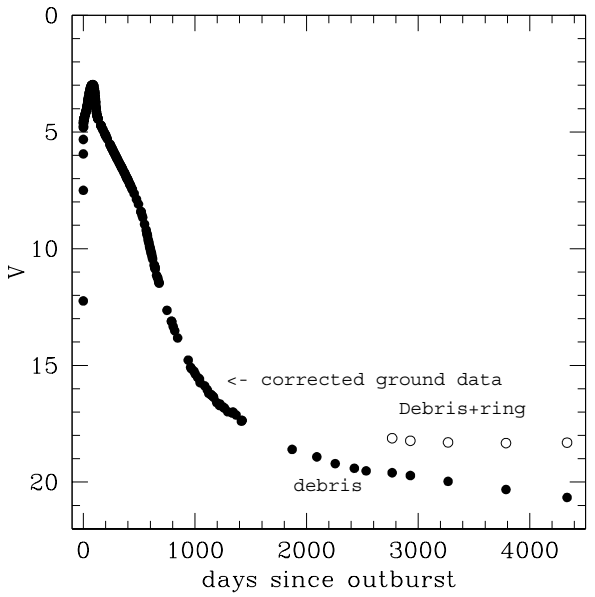

Figure 2. Light curve of SN1987A.

Light curve

SN1987A is unique in that we have recorded its light from well before it exploded until the present time ($t \approx 13$ yr). The light curve of SN1987A (figure 2) was unusual. Within hours after first detection, it brightened to $V \approx 4$. Thereafter, it continued to brighten, reaching a maximum brightness $V = 2.9$, corresponding to a bolometric luminosity $L_{\rm bol} = 10^{42}$ erg s^{-1}, at $t \approx 3$ months after explosion.

SN1987A faded rapidly thereafter. For 120 days $< t <$ 800 days, $L_{\rm bol} : e(-t/t_1)$, where t_1 agrees within a few percent with the 111.3 d mean life of ^{56}Co. This observation supports the interpretation that the supernova light is produced by reprocessing of energy deposited in the explosion debris by positrons and gamma rays from the radioactive decay of ^{56}Co. NUCLEOSYNTHESIS models predicted that a core collapse supernova explosion would produce a substantial mass of ^{56}Ni, which would decay into ^{56}Co with a mean life of 8.8 days. The observed bolometric luminosity of SN1987A during its exponential decay phase implies that the explosion debris originally contained $0.07 M_\odot$ of ^{56}Ni.

This interpretation was confirmed by the direct detection of ^{56}Co gamma ray emission lines at 847 keV and 1238 keV, which became bright enough to observe by $t \approx 200$ days. The fraction of the bolometric luminosity that emerged directly as gamma rays increased from ~1% at $t \approx 200$ days to ~50% at $t \gtrsim 800$ days. The emergent gamma rays were accompanied by a flux of hard ($\gtrsim$20 keV) x-rays that could be attributed to gamma rays degraded in energy by multiple Compton scattering in the supernova debris.

As the ^{56}Co decayed, longer-lived isotopes dominated the radioactive energy input to the debris, principally ^{57}Co (mean life 391 days) for 1000 days $\lesssim t \lesssim$ 1700 days and ^{44}Ti (mean life 78 yr) for $t \gtrsim 1700$ days.

Today, the radioactive debris of SN1987A has magnitude $V \approx 20.5$ and bolometric luminosity $L_{\rm bol} \approx 10^{36}$ erg s^{-1} (i.e. $L_{\rm bol} \approx 200 L_\odot$). Most of this luminosity emerges in the far infrared (10–100 μm) band.

The integrated bolometric luminosity of SN1987A, $E_{\rm rad} \approx 8.6 \times 10^{48}$ erg, is dominated by the radioactive decay of $0.07 M_\odot$ of ^{56}Co. (Most of the energy deposited by the earlier decay of ^{56}Ni was converted to kinetic energy of the expanding envelope.)

Models for the optical, x-ray and gamma ray light curves require that the supernova debris have a mass ~(5–15)$M_\odot$, most of which must be hydrogen and helium.

The newly synthesized elements remained mostly in the inner part ($V \lesssim 2500$ km s^{-1}) of the supernova debris. However, the early emergence of gamma rays implies that a small fraction of the newly synthesized ^{56}Ni was deposited near the outer layers of the supernova debris. Evidently, instabilities developed during the propagation of the supernova blast through the stellar envelope, disrupting the laminar segregation of nucleosynthesis products that may have existed before the explosion.

Evolution of the debris

The optical display of the supernova commenced when the blast reached the photosphere of the progenitor, ~2 h after the core explosion. As the blast emerged, the photosphere was heated to ~10^6 K and produced a flash of $\approx 10^{57}$ ionizing photons during the following several hours.

At $t \approx 1.6$ days, the spectrum of SN1987A was dominated by a blue continuum, with color temperature $T^{\rm C} \approx 14\,000$ K, punctuated by strong P-Cygni lines of hydrogen and MgII λλ2800. The blueshift of the MgII λλ2800 absorption feature indicated that the gas immediately above the photosphere was expanding with radial velocities ~30 000 km s^{-1}. The photosphere cooled rapidly thereafter, with color temperature stabilizing at ~5500 K after about 2 weeks. The maximum observed blueshift in the absorption lines decreased rapidly as the supernova expanded, indicating that the photosphere was moving inward with respect to the debris and that the gas above the photosphere was becoming transparent. The radius of the photosphere reached a maximum ~100 AU at $t \approx 3$ months, at which time the absorption lines indicated a radial expansion velocity ≈2500 km s^{-1}.

From observations of the absorption lines during the photospheric phase ($t \lesssim 4$ months), one can infer that the debris has kinetic energy $E_{\rm kin} \approx 1.5 \times 10^{51}$ erg, roughly 200 times $E_{\rm rad}$.

By $t \approx 4$ months, the photosphere had vanished and the nebular phase commenced, in which the optical spectrum was dominated by emission lines, principally Hα, [OI] λλ 6300, [Ca II] λλ 7300 and Ca II λλ 8600. The width

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

(FWHM) of the emission lines implied that most of the optical emission was produced within a sphere expanding with velocity ~2500 km s^{-1}, evidently the volume in which most of the radioactive energy is deposited. By this time, the outer part of the debris, which contains more than half the mass and most of the kinetic energy, had become invisible at optical wavelengths.

The inner debris cooled rapidly, as indicated by infrared emission from vibrationally excited CO, which first appeared in the spectrum at $t \approx 4$ months and remained prominent for several months thereafter.

At $t \approx 1$ yr, the optical and near-infrared emission lines faded rapidly and a strong far-infrared ($\lesssim 4$ μm) continuum appeared. Evidently, dust clouds formed in the inner debris and obscured roughly half of the optical and near-infrared emission from the emitting region, re-emitting the absorbed luminosity as far-infrared continuum. The fact that the redshifted sides of the emission lines (which come from the far hemisphere of the line-emitting region) are obscured more heavily than the blueshifted sides (from the near hemisphere) implies that the dust clouds are located within the line-emitting region. As yet, no spectral features have been detected in the absorption or emission by the dust that would enable us to recognize its composition.

By analyzing the emission line spectrum during the nebular phase, one can infer the physical conditions in the emission line region. The analysis shows clearly that the debris is chemically heterogeneous, with regions of different element composition having different evolutions of density and temperature. The regions composed primarily of oxygen and carbon cooled first as a result of infrared emission by CO molecules. By $t \approx 4$ yr, most of the line-emitting region had temperatures <200 K, except the helium- and hydrogen-rich zones, which had temperatures ~500 K and ~700 K, respectively. Today, the entire line-emitting region has temperature <100 K, and the optical and near-infrared emission lines are produced mainly by delayed recombination and non-thermal positrons from ^{44}Ti decay.

The fact that optically thick infrared emission lines from Fe, Co and Ni were bright at early times ($t \sim 1$ yr) implies that the zones containing newly synthesized ^{56}Ni and its decay products must occupy ~50% of the line-emitting region. Since these elements constitute only ~1–2% of the mass of this region, we conclude that the line-emitting region must have a foamy texture, in which bubbles of relatively low-density Ni–Co–Fe gas are embedded in a more dense substrate of C–O, H, He and other elements. This foamy structure is caused by radioactive heating and expansion of the Fe–Co–Ni gas due to ^{56}Ni decay during the first few weeks after the explosion.

Today, the debris has been resolved with the Hubble Space Telescope. The emitting region has a mean angular diameter ~0.25 arcsec, consistent with a mean expansion velocity ~2500 km s^{-1}. The image is slightly (~1.2:1) elongated with the major axis oriented roughly NS. It has an irregular morphology, probably because of differential obscuration by embedded dust clouds.

Circumstellar matter and progenitor star

Beginning at t=80 days after outburst, narrow (FWHM $\lesssim$20 km s^{-1}) optical and UV emission lines of Hα and more highly ionized species such as He II, N V, N IV, N III, O III and C III began to appear in the spectrum of SN1987A. These emission lines brightened to maximum luminosity $L \approx 3.5 \times 10^{36}$ erg s^{-1} by t=400 days and faded rapidly thereafter. Images taken later with the Hubble Space Telescope (figure 1) show that the source of these emission lines is a narrow elliptical ring centered on the supernova, with major (EW) and minor (NS) diameters of 1.66 arcsec and 1.21 arcsec respectively. It is now clear that this inner ring is actually a nearly circular ring of emitting gas of radius 0.67 ly, inclined at about 45°. This inner ring began to produce narrow emission lines when it was illuminated by the flash of ionizing radiation produced during the first few hours after the supernova explosion.

The narrow emission lines reached maximum light after a delay corresponding to the difference of path length from the supernova to the far (S) side of the tilted ring and then to Earth and the path directly from the supernova to Earth. This delay enables us to infer the physical diameter of the ring, which we may compare with the angular diameter to infer the distance of the supernova. The result is $D \approx 51 \pm 3$ kpc.

The inner ring is expanding, with radial velocity ~ ≈10 km s^{-1}. Assuming that the ring was expelled by the progenitor star, we estimate that this event occurred ≈20000 yr before the supernova event.

Analysis of the emission line spectrum of the inner rings shows that the abundance ratio of (C + N + O)/H is about 0.3 times the solar ratio, consistent with LMC abundances. However, the rings are nitrogen rich, with N/(C + O) about 10 times greater than the solar ratio. The enhanced nitrogen abundance is believed to be due to conversion of C and O to N through the CNO cycle in the supernova progenitor before the circumstellar ring was expelled.

After being ionized and heated by the initial supernova flash, the circumstellar rings have faded as the gas has cooled and recombined. Today, the inner ring has magnitude $V \approx 18.5$, about a factor of 10 fainter than it was at maximum light (t=400 days). From the fading rate of the emission lines, we infer that the gas in the rings has atomic densities in the range ~$(0.6–3.3) \times 10^4$ cm^{-3}, and from the brightness we infer that the glowing gas in the inner ring has mass ~$0.04 M_\odot$.

As well as the inner ring, SN1987A is surrounded by an even more remarkable pair of outer loops that are not

concentric with the supernova. We believe that these loops are actually also circular rings with approximately the same polar axis as the inner ring, but not coplanar with the inner ring. If so, the outer loops have physical radii ~1.5 ly and lie on planes approximately parallel to the plane of the inner ring but displaced by ±~1.3 ly.

The radial velocities of the outer loops are consistent with the interpretation that they too were expelled ≈20000 yr before the supernova explosion.

The origin of the triple ring system remains a mystery. Since we see similar morphologies in some PLANETARY NEBULAE, many of which have binary central stars, we suspect that the progenitor of SN1987A was also a binary system. Perhaps the rings were expelled when these stars merged. The merged binary hypothesis may also explain why the progenitor of SN1987A was a blue giant star, in contrast to most known SNeII, which result from the explosions of red giant stars.

The glowing ring system is only part of the complex and as yet poorly understood distribution of circumstellar gas around the supernova. About 2 yr after the explosion, diffuse nebulosity was detected beyond the outer loops. The most prominent part was an arc called 'Napoleon's Hat', the top of which is about 5 arcsec N of the supernova and the brim of which extends about ±5 arcsec E and W of the supernova. These diffuse features changed rapidly and vanished after about 4 yr. They are light echoes caused by scattering of the supernova light by dust grains. The dusty gas was probably expelled by the supernova progenitor when it was a red giant star. In contrast to the circumstellar rings, we can now see no trace of the gas associated with the light echoes.

The initial flash of the supernova was sufficient to ionize only ~1$M_{\odot}$ of circumstellar matter. Therefore, it is likely that the glowing gas we see in the circumstellar rings is ionization bounded and resides on the inner surface of a greater mass of still invisible gas. The key to understanding the origin of the circumstellar rings may be in the detection of this gas.

In addition to the echoes from dust nearby the supernova, astronomers detected several much larger (angular radii ~0.5–1 arcmin) expanding rings of light after about 1 yr that remained visible for several years. From the apparent superluminal velocities, one can infer the distances from the supernova of the intervening dust clouds. The clouds responsible for the brightest two echoes are at distances ~130 and ~360 pc. They have no causal connection to the supernova.

From supernova to supernova remnant

At t=2 days, non-thermal radio emission was detected from SN1987A, evidently the result of acceleration of relativistic electrons accelerated due to shocks produced by the supernova blast in the wind of the blue giant progenitor. This radio emission reached maximum at t=4 days and then faded from view after a few weeks.

Non-thermal radio emission reappeared at t≈1250 days after explosion and has continued to brighten ever since. The radio image shows that the radio source is concentrated in two lobes to the east and west of the supernova. The centers of the lobes are located between the supernova and the inner ring and they are moving with transverse velocities of ~3000 km s^{-1}.

At nearly the same time, a steadily increasing flux of soft x-rays was detected from SN1987A. Observations with the CHANDRA observatory in October 1999 showed that the x-ray image was also an annulus, roughly coincident with the radio image. Like the radio image, the x-ray image is brightest toward the east. See figure 3.

Evidently, the radio and x-ray emissions are the result of the interaction of the supernova blast with circumstellar matter inside the inner ring. Models to account for the x-ray flux from the shocked gas require that the circumstellar matter must have atomic density ~100 cm^{-3}.

Freely expanding neutral hydrogen atoms in the outer supernova debris emit Lyα and Hα as they cross a reverse shock and enter the interaction zone. Imaging and spectroscopic observations of this emission with the Hubble Space Telescope show that the reverse shock is located at a radius ~75% of the inner circumstellar ring and that the emitting atoms have radial velocities ~15 000 km s^{-1}.

In 1995, a 'hot spot' appeared on the inner ring. It has brightened steadily ever since. Beginning in November 1998, many new hot spots began to appear on the inner ring (figure 4) and to brighten rapidly, with e-folding timescales ranging from ~1–2 years. Doppler shifts and widths of emission lines from the hotspots indicate that they are caused by shocks with velocity ~250 km s^{-1}.

The hot shocked gas drives a blast wave ahead of the reverse shock. Evidently, this blast wave is entering the circumstellar ring at the hot spots, which are inward protrusions of the ring. More hot spots will appear. Several years from now, they will merge to cover the entire inner ring.

The slope of the x-ray light curve increased rapidly sometime around 1998 (figure 3). Moreover, recent (May 2002) observations with the Chandra observatory show that the x-ray image is brightest near the optical hot spots, suggesting that the x-ray emission is now dominated by the impact of the blast wave with the circumstellar ring. The x-rays cannot come from exactly the same place as the optical emission, however, because the shocks responsible for the optical emission are too slow to produce observable x-ray emission. Evidently, shock velocities ranging from ~250–2500 km s^{-1} exist near the hot spots.

The appearance of these hotspots heralds the birth of SUPERNOVA REMNANT 1987A, the stage when its luminosity is dominated by the conversion of the kinetic energy of the debris to radiation as a result of interaction with circumstellar matter. During this stage, the supernova will brighten by factors ~10^3 in radio, infrared and x-rays as well and will remain bright for many decades. After a few years, the number of ionizing photons from the shock interaction will be comparable with the initial flash of the supernova. These photons will cause heretofore unseen circumstellar matter to become visible, giving us a new opportunity to understand the complex history of mass loss from the progenitor star.

Sometime between AD 2020 and AD 2030, we will begin to see sudden changes in the optical, ultraviolet, and x-ray spectra of SN1987A, as the newly synthesized elements in the inner debris begin to cross the reverse shock. Analysis of the subsequent evolution of the spectra will give us a 3-dimensional picture of the distribution of supernova nucleosynthesis products in the supernova debris.

The compact object

Perhaps the outstanding mystery of SN1987A is the absence of any evidence (since the initial neutrino flash) for a compact object at its center. The bolometric (mostly infrared) luminosity of the entire envelope is now $L_{\rm env} \lesssim$ few$\times 100 L_\odot$, and a brighter compact object could not have escaped detection. If the compact object is a neutron star, it must be very faint—perhaps because it has an anomalously low magnetic field and/or spin rate—and it must accrete $\lesssim 10^{-11} M_\odot\,{\rm yr}^{-1}$.

Although the duration of the neutrino flash indicates that a neutron star formed during the supernova explosion, it is possible that enough matter fell back in the subsequent hours or days to cause it to collapse into a BLACK HOLE.

There is little chance of detecting a compact object in the SN1987A with radio ($\gtrsim$1 cm), ultraviolet or x-ray observations, since the debris will probably remain opaque in these bands for decades. The compact object might also remain obscured at optical and infrared wavelengths if it happens to lie behind one of the dust clouds in the inner debris. The best chance might be to detect pulsations at millimeter wavelengths, but this will require a telescope array with much better angular resolution and sensitivity than those currently available.

Supernova Remnants

A supernova remnant (SNR) is the aftermath of a stellar explosion, including interstellar gas swept up in a shock wave, the expanding stellar debris and in some cases a compact stellar remnant. Some SNRs are powered by pulsars, while others show no sign of a neutron star or black hole. The typical kinetic energy of an SN explosion is 10^{51} erg. A strong shock wave transforms much of this energy into thermal energy and cosmic ray energy. As the SNR ages, more and more of the thermal energy is lost to radiative cooling, the shock slows down, and the shell of shocked gas merges back into the interstellar medium (ISM). During the course of this evolution, an SNR can be observed as an expanding shell of hot gas containing many solar masses and emitting as much as 10^{39} erg s^{-1} throughout the radio to γ-ray wavelength range.

SNRs disperse the elements produced in the cores of the pre-supernova stars, along with those produced by explosive nucleosynthesis, through the ISM. Thus the synthesized elements are available for a new generation of star formation. Some of these elements may take the form of dust grains, and others will occur as neutrals or low-charge ions. During the course of its evolution, the interaction of the SNR with the ISM reheats the SN ejecta, disrupting dust grains and ionizing the ejected material.

The energy of SNRs is important for the overall structure and evolution of the ISM. The fast shock waves of a young SNR heat the interstellar gas to millions of kelvins, and it expands to produce a vast bubble of tenuous gas. When the shock speed falls below about 300 km s^{-1}, radiative cooling becomes effective in removing the thermal energy. The remaining energy goes into compressing the magnetic field, turbulent motion or cosmic ray acceleration.

SNRs are often observed as shells of hot gas a few parsecs to tens of parsecs in size. They produce x-rays at 100–10 000 eV photon energies by electron–ion collisions in hot gas or by synchrotron emission. Many SNRs have been discovered through their polarized radio emission, and γ-rays have been detected in a few cases. The appearance in optical images ranges from tiny, fast knots of pure oxygen to delicate filaments of pure Balmer line emission. SNRs produce infrared emission from dust grains heated by collisions with shock-heated electrons and ions. The cold gas in SNRs produces strong IR emission in atomic fine structure forbidden lines and molecular transitions.

The following sections summarize the different classes of SNRs. Eventually, when the mass of material swept up from the ISM is much greater than the mass ejected in the stellar explosion, the character of a remnant is determined mostly by its age and the density structure of the interstellar gas it encounters. However, for the first thousand years or so of its life, the SNR is strongly influenced by the nature of the explosion. SUPERNOVAE themselves are divided into two broad classes. Type Ia SNs are thermonuclear explosions of white dwarfs, while type II SNs occur when the core of a massive star collapses. Type Ib and Ic SNs resemble type I events in some ways, but they result from the core collapse of a star that has lost its hydrogen envelope. All types of SNs inject energies of order 10^{51} erg, but the masses involved are very different. A type Ia SN ejects $1.4M_{\odot}$ of iron-rich material, while a type II SN ejects an order of magnitude more material at lower speeds. Type II SNs can leave compact remnants, either black holes or neutron stars. In some cases the neutron star is a strong pulsar, able to dominate the energetics of the SNR for many years.

Young SNRs

SNRs younger than about 1000 yr show strong signatures of their origins. SN1987A provides the opportunity to study the very early evolution of an SNR as it interacts first with material shed by the precursor star and later with the ambient interstellar gas. The differences in ejected mass and composition and the presence or absence of a PULSAR lead to three basic types of young SNRs.

Type Ia SNRs (Balmer line remnants)

These are the simplest SNRs, appearing as nearly circular, limb-brightened shells in x-ray and radio emission. The prototypes are the remnants of the supernovae reported by Tycho Brahe in 1572 and by Chinese astronomers in 1006. Four SNRs of this class are known in the Large Magellanic Cloud.

The SN ejecta cool very rapidly by expansion, becoming a cloud of extremely cold, nearly neutral gas expanding at thousands of km s^{-1} into the ISM. A hot star observable at ultraviolet wavelengths is fortuitously located behind SN1006, and observations with IUE and the Hubble Space Telescope show strong absorption in lines of Fe II and Si II spread over a velocity range of $\pm$4000 km s^{-1}.

When the cold ejecta encounter the ISM at highly supersonic speeds, a shock wave forms in the interstellar gas and a another shock (the 'reverse shock') forms in the ejecta. The shocks compress the ISM and ejecta and heat them to temperatures $\simeq 10\ \mu V^2$, where μ is the mean atomic weight of the shocked gas and V is the shock speed in km s^{-1}. Thus the SNR at this stage consists of a cold, rapidly expanding inner region surrounded by a shell of shocked SN ejecta, which is in turn surrounded by a shell of shocked interstellar gas. The pressures of the shocked ejecta and shocked ISM balance, and a contact discontinuity separates the two regions.

The structure of the shell of shocked gas depends on the density structure of the ejected gas, but in general the shocked ejecta are cooler and denser. The entire shell of shocked material decelerates as it sweeps up mass from the ISM, and the contact discontinuity between the shocked ISM and shocked ejecta is subject to the Rayleigh–Taylor instability, which mixes the two components and generates dense clumps. The Rayleigh–Taylor instability is seen on Earth when a low-density fluid supports a dense fluid against gravity. In the SNR, deceleration of the shell of shocked gas plays the role of gravity.

The shell of shocked gas produces bright x-ray emission. The shocked ejecta, being highly enriched in iron and other moderately heavy elements, produce x-ray radiation more efficiently, and the emission of this gas is further enhanced by its high density. X-ray spectra in the 1–10 keV photon energy range show strong emission lines of highly ionized Si, S, Ca and Fe produced by impact of thermal electrons on the ions. Continuum emission at moderate x-ray energies arises from bremsstrahlung and from radiative recombination of ions and electrons. The shocked ISM is somewhat hotter and produces more emission at x-ray energies above 10 keV.

Strong shock waves can accelerate particles to relativistic energies. Their velocity distribution takes the form of a power law. Ions accelerated by SNR shocks constitute a large part of the cosmic ray population. Energetic electrons spiraling in the magnetic field produce a polarized radio continuum of SYNCHROTRON RADIATION. As both the magnetic field and the non-thermal particle densities are concentrated in the shell of shocked material, type Ia SNRs appear as strongly limb-brightened shells at radio wavelengths, well correlated with the x-ray emission.

The non-thermal electrons can also produce hard x-ray and γ-ray emission. SN1006 shows bright arcs of hard x-rays produced by synchrotron emission, and TeV γ-rays, believed to be produced by inverse Compton scattering from energetic electrons, have been detected from one of these arcs. The non-thermal x-rays are a continuation of the radio spectrum, but with a steeper spectral slope. Comparison of the radio and x-ray emission constrains the acceleration time of the particles and the magnetic field strength.

Type Ia SNRs are faint at optical wavelengths. They show only thin filaments along parts of their peripheries. The spectra of these filaments are remarkable in that the only optical emission detected is the H I Balmer series. This is in sharp contrast to the usual spectra of photoionized or shock-excited nebulae, where the forbidden lines of [O I], [O II] and [O III] dominate. The shocks in Type Ia SNRs are extremely fast. Radiative cooling is ineffective, and the hot gas produces very little emission at optical wavelengths. However, if the shock encounters partially neutral material, each hydrogen atom swept up by the shock stands about a 20% chance of being excited to produce an Hα photon before it is ionized. It may also undergo charge transfer with an ion in the shocked gas. Thus the Hα line profile consists of a narrow component, with a the velocity width of the pre-shock gas, and a broad component whose width is that of the ions in the shocked gas. The profile of one filament in Tycho's SNR has a narrow component 44 km s^{-1} wide (full width at half-maximum) and a broad component 1900 km s^{-1} wide. These line profiles are useful for measuring the shock speed and for examining the physical processes in the shock. Shock speeds of the known type Ia remnants range from 500 to 2300 km s^{-1}.

Type II, Ib and Ic SNRs (oxygen-rich remnants)

In a few young SNRs, fragments of the core of the progenitor star are visible. They appear as knots of material completely devoid of hydrogen and helium. As products of massive stars, these SNRs often occur in or near dense molecular clouds. Some are badly obscured by dust, and interaction with a cloud may complicate the structure.

The best-known example of this class is Cas A (CASSIOPEIA A). Like the type Ia SNRs, the O-rich remnants display a forward shock–reverse shock structure. The SN event ejects tens of solar masses of material that has undergone nuclear burning. In some cases an outer envelope of unprocessed material is ejected as well. Both the radio and the x-ray emissions from the shocked shell are very bright, and they are concentrated in small knots. X-ray, optical and radio brightness are well correlated on large scales, but individual knots do not match knots seen at other wavelengths. The high degree of clumping is likely to result from advanced Rayleigh–Taylor instability. Thermal emission dominates the x-ray spectrum. Non-thermal emission may be present as well, but the brightness of the thermal emission makes it more difficult to disentangle than in the type Ia SNRs. The recent discovery of γ-ray emission from the decay of ^{44}Ti from Cas A opens a new avenue for the study of core collapse in supernovae.

A remarkable aspect of the O-rich remnants is the swarm of fast knots at optical wavelengths. Cas A shows several hundred of these knots, which can appear and fade over the course of a decade. In Cas A, they show pure oxygen emission, oxygen mixed with sulfur, and in some cases C, Ar and Ca as well. Little neon is seen in optical spectra, but [Ne II] and [Ne III] have been detected in infrared spectra. Infrared continuum emission from dust grains at temperatures near 200 K has also been detected from the knots.

The Cas A knots travel at around 6000 km s^{-1}. Their proper motions and Doppler shifts can be fitted to nearly spherical expansion originating at a point in about 1658. By combining the line-of-sight component of velocity obtained from the Doppler shifts with the component in the plane of the sky (obtained from proper motions), it is found that the knots lie on a roughly spherical surface. Still more remarkable, most of them fall on several large circles on that sphere.

The knots in Cas A are believed to be clumps formed during the SN explosion. Initially they move more slowly than the more tenuous gas of the outer envelope of the exploding star. As the SNR sweeps up interstellar gas, the outer layers slow down and the knots overtake the reverse shock. When that occurs, a slower shock propagates into the dense knot. Models for the infrared, optical and ultraviolet emission from such shocks are not entirely consistent with the observed spectra, but in general the shock wave thermalizes the bulk kinetic energy of the ions. Coulomb collisions gradually transfer this energy

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

to electrons, which ionize and excite the ions to produce the observed emission.

Cas A also shows other types of emission knots. Relatively slow knots rich in He and N (quasi-stationary flocculi) are interpreted as material shed by the SN progenitor during an earlier red giant phase of its evolution. When the blast wave encounters dense clumps of this material, it drives relatively slow shocks ($\simeq$150 km s^{-1}) into them. There are also a few high-velocity knots which show He- and N-rich spectra. Some of these lie in a high-velocity jet in the northeast which extends beyond the apparent boundary of the rest of the remnant.

Other examples of the O-rich class are N132D and 1E102.2-7219 in the MAGELLANIC CLOUDS and G192+1.8 in the plane of the Milky Way. An extremely luminous oxygen-rich remnant in the irregular galaxy NGC4449 is unresolved even in Hubble Space Telescope images. N157 shows O-rich knots along with a pulsar. A few knots of processed material are found in the somewhat older remnant Puppis A.

The Magellanic Cloud remnants are the best-observed of these objects thanks to the relatively low extinction in those directions. Their UV spectra indicate more neon than Cas A, along with lines of carbon, oxygen and magnesium. The ratios of ultraviolet to optical line intensities imply electron temperatures of order 30 000 K, confirming the basic idea of excitation in modest velocity shocks.

Crab-like SNRs

The CRAB NEBULA is a spectacular example of a pulsar-driven SNR. It is unique in many ways, although a few related SNRs are known. The Crab was created in an explosion reported by Chinese astronomers in the year 1054. It is an irregular system of rapidly expanding filamentary emission and an amorphous cloud of polarized synchrotron emission observed from radio through γ-ray wavelengths. This emission is powered by the pulsar, which produces a relativistic wind. Shock waves in this wind can appear as moving wisps.

The network of optical filaments occupies a thick shell expanding at 700–1800 km s^{-1}. These filaments emit the usual nebular forbidden lines, the hydrogen Balmer lines and helium recombination lines. They show signs of modest nuclear burning, particularly enhanced helium abundances. The composition suggests a progenitor mass of order $8M_\odot$.

The spectra of the optical filaments are generally consistent with heating and ionization by synchrotron continuum photons. Photoionization alone leads to relatively faint emission of ultraviolet spectral lines, however, and ultraviolet observations imply that some shock heating is also required. Shock heating and photoionization are intertwined in the physics of the optical filaments. The expanding relativistic cloud drives 100 km s^{-1} shocks into the smooth cloud of SN ejecta. As the gas cools, it produces UV line emission, and in the process of cooling it becomes more dense, increasing its emissivity when exposed to ionizing photons. The Rayleigh–Taylor instability condenses the cooled gas into sheets and fingers.

The unshocked outer regions of the stellar ejecta are extremely faint owing to their low density. They have not yet encounted dense enough interstellar gas to have formed a detectable forward–reverse shock pair. A cylindrical structure of optical emission filaments resembling a chimney protrudes beyond the shell defined by the other optical filaments. Apparently, compression makes the outer ejecta visible there.

SNRs similar to the Crab include 3C58 and CTB87. They are characterized by non-thermal emission with a relatively flat spectrum at radio wavelengths. While the type Ia and oxygen-rich remnants show limb-brightened shell structures, the surface brightness of a Crab-like remnant peaks at the center near the pulsar. The best-studied of these objects, 3C58, has faint optical emission filaments like those of the Crab and an extended x-ray emission region. It may be the remnant of an SN explosion in the year 1181.

A number of other SNRs contain pulsar-powered radio and x-ray nebulae along with shells of thermal emission. These hybrids include N157 (mentioned above for its extreme elemental composition), CTB80, MSH15-56 and the Vela SNR. Pulsars are not always apparent, perhaps because of the beaming of the pulsar radiation in another direction. W50, the SNR containing SS433, shows apparently normal shock heating at its boundaries, but the non-thermal emission is also present.

The rarity of SNRs like the Crab indicates that they represent a very short stage in the life of an SNR or that they are formed only by an unusual type of explosion.

Older SNRs

After an SNR has swept up much more interstellar gas than the mass of the stellar ejecta, the character of the explosion itself becomes unimportant. The explosion energy and the density of the ambient material determine the evolution and appearance of the SNR. For a typical SN energy of 10^{51} erg and an interstellar density of 1 cm^{-3}, an SNR loses the memory of its origin after a few thousand years.

For expansion of a blast wave in a uniform medium, the Sedov–Taylor similarity solution predicts the radius and velocity of the shock as a function of time. Conservation of energy determines the basic evolution. The relations are

$$R = 13.6(\epsilon_{51}/n_0)^{1/5} t_4^{2/5} \text{ pc} \quad (1)$$

$$V = 535(\epsilon_{51}/n_0)^{1/5} t_4^{-3/5} \text{ km s}^{-1} \quad (2)$$

where ϵ_{51} is the SN explosion energy in units of 10^{51} erg, n_0 is the ambient density in atomic mass units per cm^3 and t_4 is the age divided by 10 000 yr. The post-shock temperature is proportional to the square of the shock speed, so that $T = 3.1 \times 10^6 (\epsilon_{51}/n_0)^{2/5} t_4^{-6/5}$ K at the edge of the remnant. The profiles of density, temperature and velocity inside the SNR are invariant functions of the fractional radius. The mass is concentrated near the outer edge, so that the SNR

appears as a limb-brightened shell with a temperature a little above the shock temperature at a given time.

As the shock slows to about 300 km s^{-1}, the radiative cooling time becomes comparable with the age of the remnant. The infrared luminosities exceed the x-ray luminosities in many remnants, though recent IR observations show that much of the IR flux is forbidden line emission from cold gas, rather than emission from hot dust grains in the hot regions. When a significant fraction of the SN energy is radiated away, the temperature and pressure drop. A substantial fraction of the energy emerges as UV and extreme UV photons, many of the latter being absorbed by the surrounding gas. When a large part of the thermal energy of the remnant has been lost, slower expansion continues in the 'snow-plow' phase, where conservation of the momentum of the cold SN shell governs the expansion.

Several variants of the Sedov–Taylor picture have been computed, including ambient densities which vary with distance from the explosion or physical effects, such as thermal conduction and cosmic ray pressure. Especially in the later phases, the INTERSTELLAR MAGNETIC FIELD can play a major role in supporting the cool gas against compression.

Before the onset of strong radiative cooling, an ideal Sedov SNR would appear much like a type Ia SNR. The model predicts a limb-brightened shell at x-ray and radio wavelengths, with a thin layer of faint optical and ultraviolet emission from the ionizing gas just inside the shock front. Infrared emission from heated dust grains should be closely correlated with the x-ray shell.

Because of the relatively high density and low temperature near the edge of the SNR, radiative cooling affects that region first. A bubble of hot, x-ray-emitting gas remains in the interior, and shocks slower than about 300 km s^{-1} produce bright optical and UV emission. Strong shocks heat the interstellar gas to $1.4 \times 10^5\ v_{100}^2$ K (where v_{100} is the shock speed in units of 100 km s^{-1}), ionize it and accelerate it to three-fourths of the shock speed. In the idealized picture, the gas cools at nearly constant pressure, becoming more dense as it does so. As the density increases, the cooling speeds up, and the temperature drops steeply to around 10 000 K. At that point, hydrogen recombines, and the neutral gas begins to absorb ionizing photons from the hotter regions upstream. This maintains an ionized layer much like an H II region in appearance until the ionizing photons are exhausted.

The rapid cooling and high density cause the emission from the cooling shock to occur in a narrow layer behind the shock. Thus the shock produces a thin sheet of glowing gas at the edge of the SNR. Ripples in the sheet viewed close to edge on take on the appearance of narrow filaments, with diffuse emission between. The bright filaments correspond to tangencies between the line of sight and the emitting sheet of gas, and in those places the flow velocity is transverse to the line of sight. Figure 1 shows a shock wave that has recently entered the cooling phase. As the shock evolves, the crisp arcs become more fragmented and diffuse.

Figure 1. Hα image of a shock front in the Cygnus Loop from the Hubble Space Telescope. The thickness of the rippled sheet of emitting gas unresolved even at the 0.1″ WFPC2 resolution. The long dimension of the image is 2.7 arcmin. (Image courtesy of W P Blair.)

The optical spectrum of the radiatively cooling shock is similar to that of a photoionized nebula, except that a broader range of ionization states is present. The [O III] lines dominate the spectra of most H II regions, while [O I], [O II] and [O III] lines are all bright in SNR shocks. There are also indicators of high temperatures in shocked gas, in particular the temperature-sensitive ratio of the λ4363 and λ5007 forbidden lines of [O III]. The ultraviolet emission lines from a shock are far stronger than those from photoionized gas, as the radiative cooling process mainly converts thermal energy into UV photons. The lines C III λ1909, C IV $\lambda\lambda$1548, 1551 and O VI $\lambda\lambda$1032, 1037 are especially bright. As the temperature falls to about 1000 K, much of the cooling occurs by way of infrared fine structure transitions. ISO observations reveal strong emission in the lines [C II] 157 μm, [O I] 63.2 μm, [Ne II] 12.8 μm, [Si II] 34.8 μm and [Fe II] 26.0 μm. The IR, optical and UV spectra provide diagnostics for the density, temperature and elemental abundances in the shocked gas.

As the SN shell continues to sweep up mass from the ISM, the shock slows still further. Eventually, at shock speeds of order 10 km s^{-1}, much of the emission emerges as molecular emission in the infrared. The 2.12 μm line of H_2 is the most easily observed signature of such shocks. Lines of CO and other molecules are seen at radio wavelengths.

Older SNRs produce a polarized radio continuum by synchrotron emission much like that of the young SNRs. While the young SNRs accelerate electrons to relativistic speeds, old SNRs probably generate the observed radio emission by compressing the cosmic ray electrons and magnetic field already present in the ISM (van der Laan mechanism). A strong radiatively cooling shock compresses the gas and particles by a factor of 100 or more, enormously increasing the synchrotron emissivity. The compression amplifies the magnetic field component perpendicular to the shock flow, and the polarization of the radio emission is generally consistent with tangential magnetic fields around the SNR periphery.

This basic picture of SNR evolution can be adapted to include such effects as magnetic pressure support, electron–ion temperature differences or the gradual liberation of elements such as C, Si and Fe from dust grains by sputtering or grain–grain collisions. A more serious obstacle to the straightforward derivation of physical parameters from spectra is the instability of the shock under various conditions. A dynamical instability occurs when the hot interior gas pushes a thin shell into the surrounding medium. There is also a catastrophic thermal instability in radiatively cooling shocks faster than about 150 km s^{-1}. These instabilities are especially likely during the transition from the Sedov phase to cooling phase, and they can lead to the formation of secondary shocks.

While the Sedov picture is useful as an approximate description of SNR evolution, the ISM is not homogeneous. The blast wave in low-density interstellar gas encounters denser clouds, and these encounters determine the appearance, and perhaps the evolution, of older SNRs. When the blast wave strikes an obstacle, rapid deceleration pushes a weak shock back into the expanding hot gas, increasing the temperature, density and x-ray emissivity. At the same time, a slower shock propagates into the dense cloud. Approximate constancy of the ram pressure, ρv^2, implies that the cloud shock speed is related to the blast wave speed by the square root of the density contrast. If the cloud is large on the scale of the supernova remnant, as in the northeastern or western sides of the CYGNUS LOOP, the interaction will produce enhanced x-ray emission and bright optical filaments, and the expansion rate will be smaller than in lower-density sectors of the SNR.

If the dense cloud is small, the same pattern of x-ray enhancement and optical emission will occur for a short time, but the blast wave quickly sweeps past the cloud. A strong shear in the flow past the cloud generates turbulence, and the cloud will soon be destroyed. The turbulence also tangles and amplifies the magnetic field. This may prevent the cascade of turbulence to small scales, and it may prevent thermal conduction from evaporating the cloud material. If the turbulent cascade proceeds far enough, or if thermal conduction is effective, the cloud material can merge with the hot gas, greatly increasing its density and cooling rate. If the ISM is populated with a large number of small clouds, the rate at which dense gas enters the hot phase may govern the SNR evolution.

It is expected that many SNRs occur in atypical regions of the ISM. The massive stars that produce type II supernovae are formed from massive clouds, and they exhaust their supply of fuel before moving far from their formation sites. They also produce strong winds and powerful ionizing radiation that can modify the immediate environment. SNRs such as the Cygnus Loop are believed to have occurred inside bubbles of their own creation. The luminosity of such an SNR is very low until the blast wave reaches the dense outer shell of the bubble. Then the pressure and luminosity rise rapidly, and the remnant can be far more luminous than a Sedov remnant of the same size.

Interaction

The ultimate fate of SNRs is not known. The low-density cavity of an old SNR provides a channel for the energy of any subsequent SN explosion in or near it. If the SN rate is high enough compared with the cooling time, the tenuous gas will be reheated before it is able to cool. The result could be a system of hot tunnels in a denser ISM, or perhaps a matrix of hot, low-density gas with embedded dense clouds. On the other hand, a lower SN rate, abetted by the buffering of magnetic fields, can reduce the likelihood of interaction. In that case, the SNR shock gradually slows, the interior slowly cools and the shocked gas merges back into the ISM.

If the supernovae are highly correlated events, the odds of interaction greatly increase. The stellar winds and the high supernova rates of an OB ASSOCIATION are sufficient to maintain an enormous low-density bubble with a slowly expanding dense shell. Such a bubble may take the form of a supershell, resembling an SNR with initial explosion energy of 10 or 100 supernovae. In a disk galaxy, the shock tends to break onto the galactic halo, forming a chimney for hot gas to flow upwards. Candidate supershells have been observed in the Galaxy, the Large Magellanic Cloud and other nearby galaxies.

A possible instance of the reheating of an old SNR by a second event is the Local Bubble, a region of hot, tenuous gas about 100 pc in size engulfing the solar neighborhood. The temperature and density derived from soft x-ray measurements are difficult to reconcile with the standard model of a single SN explosion, but an old SNR cavity reheated by a subsequent explosion can explain the size and temperature of the Local Bubble.

Supernovae

Supernovae represent the catastrophic explosions that mark the end of the life of certain stars. A mass of one to ten times the mass of the Sun is ejected with velocities of about one to ten percent of the speed of light. The corresponding energy is comparable to the gravitational binding energy of a star and hence evidence that the star is severely, if not completely, disrupted. The explosion commonly ejects heavy elements that seed the gas of the interstellar medium. This enriched gas then condenses to form new stars. The heavy elements can form planets and living things. Some supernovae may produce compact remnants such as NEUTRON STARS or BLACK HOLES. Supernovae also produce extended remants as their ejecta sweep outward and drive shock waves into the interstellar medium. This energy can help to form new stars and blow matter entirely out of host galaxies in some circumstances. Because of their great brightness, supernovae can be used to determine distances and help to determine the age, shape and dynamics of the universe.

Historical supernovae

Supernovae have been witnessed in our Galaxy, but only in the historical past. Historical records, particularly the careful data recorded by the Chinese, show that seven or eight supernovae have exploded over the last 2000 years in that portion of the Galaxy not obscured by dust, about 15% of the area of the galactic plane. We also see the expanding supernova remnants that have been produced by supernovae. The youngest of these correspond to the historical supernovae, but we also observe the effects of several hundred older SUPERNOVA REMNANTS that have exploded over the last million years or so.

The supernova of 1006 was the brightest ever recorded, brighter than Venus and perhaps as bright as a quarter Moon. It was observed throughout the Middle and Far East. The supernova of 1054 is by far the most well-known. This explosion produced the rapidly expanding shell of gas that modern astronomers identify as the Crab Nebula. The supernova of 1054 was apparently recorded first by the Japanese and was also clearly mentioned by the Koreans, although the Chinese have the most careful records. There is a strong suspicion that Native Americans recorded the event in rock paintings and perhaps on pottery. There is no confirmed record of an observation in Europe. The supernova of 1572 was observed by Tycho Brahe. Tycho's discovery helped to alter the world view of immutable heavens that began to shift during the Renaissance. Tycho's student, Johannes Kepler, in his turn witnessed the explosion of a supernova in 1604. Kepler also took careful data by which we deduce that he witnessed the same kind of explosion as his mentor. Although there are counter-arguments and some controversy, both Tycho's and Kepler's supernovae are widely regarded to be the kind of event modern astronomers label Type Ia (see below).

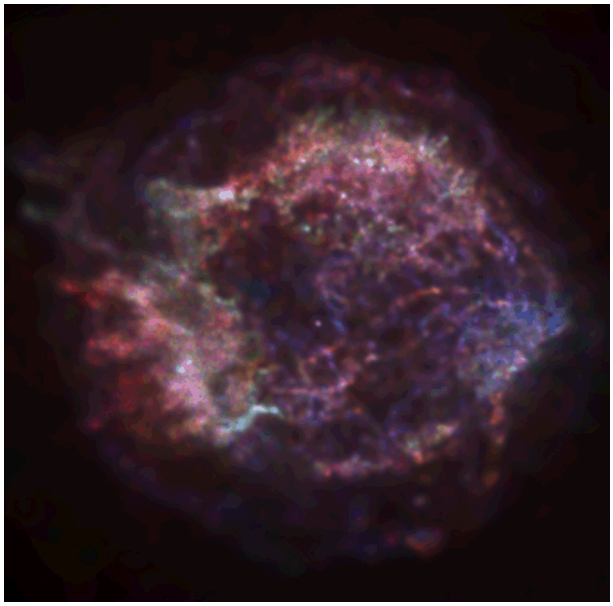

Figure 1. X-ray image of the supernova remnant Cassiopeia A obtained by the Chandra X-ray Observatory. (Courtesy of NASA.)

A young expanding gaseous remnant of an exploded star is observed as a powerful emitter of radio radiation known as Cassiopeia A (figure 1). From the present size and rate of expansion of the remnant, we deduce that the explosion that gave rise to Cas A occurred in about 1680. No bright optical outburst was seen. This explosion may have been under-luminous, but the degree is difficult to ascertain since there is a great deal of patchy dust extinction in this direction. There are reports that Cas A was seen faintly by Flamsteed, the first Astronomer Royal of England, but there are questions concerning whether or not that sighting was in the same position as the remnant observed today. Supernovae tend to be brighter if they explode within large red giant envelopes. The suspicion is that the star that exploded in about 1680 may have ejected a major portion of its envelope before exploding or that the star was otherwise relatively small and compact. That condition, in turn, may have prevented Cas A from reaching the peak brightness characteristic of most supernovae. SUPERNOVA 1987A, the best studied supernova of all time, had this property of being intrinsically dimmer than usual.

Supernova types

All supernovae observed since 1680, and hence all supernovae seen by modern astronomers, have been in other galaxies. A single galaxy produces a supernova only rarely. Supernovae occur roughly once per hundred years for SPIRAL GALAXIES like the Milky Way. Astronomers observe a huge number of galaxies at great distances. The chance that some of these galaxies will have supernovae go off in them is appreciable. Before supernova 1987A, about

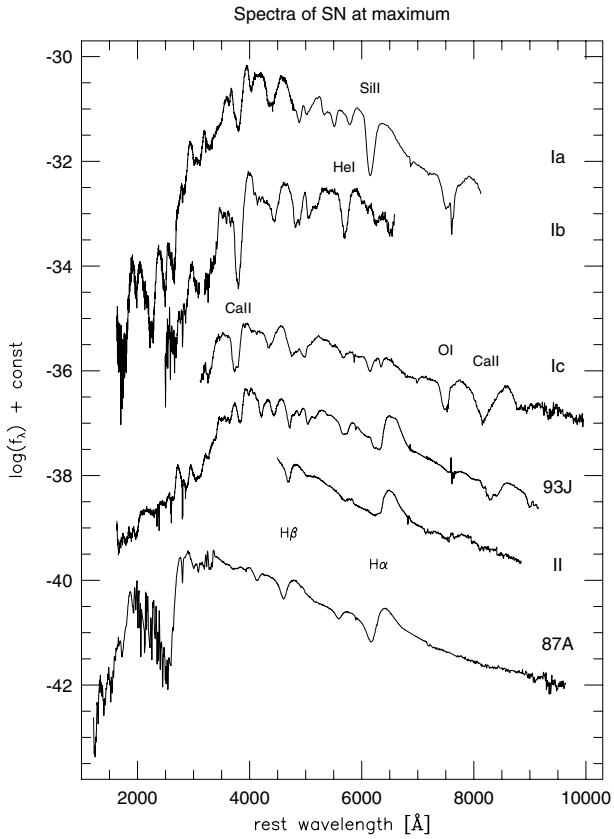

Figure 2. Characteristic spectra of various types of supernovae near maxiumum light. The features labeled are: Si II—ionized silicon; He I—neutral helium; Ca II—ionized calcium; O I—neutral oxygen; Hα, Hβ—neutral hydrogen. (Reprinted from *Astrophysical Quantities*, American Institute of Physics Press.)

30 supernovae were recorded every year. Closer attention was paid to discovering supernovae after supernova 1987A, especially at great distances where they are cosmological markers, and the current rate of discovery is about 100 per year.

Categories of supernovae are traditionally defined by the spectrum that reveals the composition of the ejected matter. Complementary information is obtained from the light curve, the pattern of rapid brightening and slower dimming followed by each event. From the studies of supernovae in other galaxies, astronomers have identified two basic types called Type I and Type II. The dividing lines of this taxonomy are blurred by events that share some properties of Type I and some of Type II (figure 2).

The spectra of Type I supernovae reveal no detectable hydrogen, the most common element in the universe. Some Type I supernovae, called Type Ia, appear in all kinds of galaxies—elliptical, spiral, and irregular. Type Ia tend to avoid the arms of spiral galaxies. Since the spiral arms are the site of new STAR FORMATION, Type Ia supernova are deduced to explode in older, longer-lived stars. This is consistent with their being the only type to explode in ELLIPTICAL GALAXIES that lack recent star formation. Type Ia show characteristic elements in the spectrum, with elements such as magnesium, silicon, sulfur, and calcium near maximum light and iron later on. The light curve for Type Ia supernovae is also characteristic. There is an initial rise to a peak that takes about two weeks and then a long slower period of gradual decay over timescales of months that is very similar for all these events. The data recorded by Tycho and Kepler suggest that they both witnessed Type Ia supernovae. For decades, all Type Ia supernovae were thought to be virtually identical, but more recent careful observations have revealed small, but real, variations among them.

Near the peak of their light output, Type II supernovae show normal abundances in their ejected material, including a normal complement of hydrogen. These supernovae have never appeared in elliptical galaxies. Type II supernovae occur occasionally in IRREGULAR GALAXIES, but mostly in spiral galaxies and then within the confines of the spiral arms. The interpretation is that the stars that make Type II supernovae are born and die in a short time. Since they are short-lived, the stars that make Type II supernovae must be massive. The optical light curve of a typical Type II supernova shows a rise to peak brightness in a week or two and then a period of a month or two when the light output is nearly constant. After this time, the optical luminosity drops suddenly over a few weeks and then more slowly with a timescale of months. This pattern of light emission with time is consistent with an explosion in the core of a star with a massive, extended red giant envelope.

Two other varieties of hydrogen deficient supernovae are labeled Type Ib and Type Ic. The two types are probably closely related. Unlike Type Ia, but like Type II, Types Ib and Ic only seem to explode in the arms of spiral galaxies. Therefore, Types Ib and Ic are also associated with massive stars. Type Ib show evidence for helium in the spectrum near maximum light. Type Ic show little or no such evidence for helium. On the other hand, both Type Ib and Ic show evidence for oxygen, magnesium and calcium at later times. Type Ib and Ic show little or no evidence for a strong line of silicon that is a major characteristic of the spectra of Type Ia. Type Ia supernovae show essentially only iron at later times, another factor emphasizing their difference from Types Ib and Ic. The composition revealed by Types Ib and Ic is similar to that expected in the core of a massive star that has been stripped of its hydrogen. In the case of Type Ic, most of the helium is gone as well. This suggests an origin of Type Ib and Ic in stars much like WOLF–RAYET STARS, but a direct connection to this class of stars has not yet been established. The light curves of Type Ib and Ic are somewhat similar to those of Type Ia, but are dimmer at maximum light. Type Ib and Ic are often strong radio sources whereas no radio has yet been detected from a Type Ia. Radio emission is thought to be created when the supernova shock collides with a surrounding medium, so this radio emission may indicate strong mass loss from

Type Ib/c, again consistent with an origin in a massive stellar core.

A bright supernova observed in 1993, SN 1993J, gave yet more clues to the diversity of processes that lead to exploding stars. SN 1993J revealed hydrogen in its spectrum, so this event was a variety of Type II. As the explosion proceeded, however, the strength of the hydrogen features diminished and strong evidence for helium emerged. In this phase, SN 1993J resembled a Type Ib. Apparently this star had most, but not all, of its hydrogen envelope removed, probably in a binary mass transfer process. There is yet no direct observational proof for binary companions in Type Ib or Type Ic or the transition events like SN 1993J, but this seems likely. Strong winds from massive stars could play a role in stripping the hydrogen and helium from Type Ib and Type Ic and the relative importance of winds versus binary mass transfer has not been resolved.

Progenitor evolution in massive stars

Type II and Type Ib/c supernovae thus represent the explosion of massive stars. These stars have presumably evolved from the main sequence to RED GIANTS and have had a series of nuclear burning stages producing ever heavier elements in the core. The masses of the stars that give rise to these events is estimated to be between about ten and perhaps thirty to fifty solar masses. Below the lower limit, stars make WHITE DWARFS that do not explode as single stars, but may explode as Type Ia if they occur in binary systems with appropriate mass exchange. Above the very uncertain upper limit, stars probably collapse to make black holes with no associated supernova explosion. The statistics of the rate of explosion of these events is roughly consistent with this estimate. Stars of this mass range are thought to form iron cores that collapse to form neutron stars. There is thus a strong suspicion that Type II and Type Ib/c supernovae make neutron stars as compact remnants of the explosion and that the gravitational energy liberated in forming the neutron star is the driving force of the explosion.

At the lower end of the mass range suspected to contribute to Type II and Type Ib/c supernovae, the evolution may be slightly different. Computer calculations show that, for stars with original mass between about eight and twelve solar masses, carbon burns to produce neon and magnesium, but the oxygen that typically co-exists with the carbon after helium burning does not get hot enough to burn. The core, now composed of oxygen, neon, and magnesium, contracts to form a white dwarf. The atomic nuclei of neon and magnesium are capable of absorbing an electron, thus turning one proton into a neutron, and transmuting themselves into an element of lower proton number. This process reduces the electrons that are responsible for the pressure that supports the core. The result is that the core collapses before any of the elements in the core begin thermonuclear burning. During the collapse, the remaining nuclear fuels—oxygen, neon, and magnesium—are converted to iron. The net result is a collapsing iron core, just as for the more massive stars where the iron core forms before the collapse ensues. These two processes of iron core collapse may give identical results, or there may be some subtle difference between collapse triggered by absorbing electrons rather than by heating and disintegrating the iron. These differences could affect the explosive outcome.

Estimates of the rate of formation of neutron stars in the Galaxy are similar to estimates of the rate of formation of Type II and Type Ib/c supernovae. This does not prove that these supernovae produce neutron stars, but the notion that the two processes are directly related is a nearly universal working hypothesis.

Nuclear synthesis in massive stars

Theoretical calculations show that heavy elements in reasonable proportions are produced naturally in massive stars in the process of forming an iron core. Stars with mass between about 15 and 100 solar masses produce substantial amounts of heavy elements. If these stars explode and eject their heavy elements, this freshly synthesized material will mix with the hydrogen in the interstellar gas. New stars form from this enriched mixture. Stars in the upper end of this range could collapse to form black holes without substantially altering this picture.

Core collapse

The iron core that forms in the center of a massive star is endothermic; it can only absorb energy either by breaking down into lighter elements or by forging heavier elements. The absorption of energy reduces the pressure support and guarantees that the iron core will become unstable to collapse shortly after it forms, in less than a day. In practice, the dominant process that destabilizes the core is that of photodisintegration, when photons of light (actually gamma-rays in the hot interior of the core) cause some of the iron to break apart into helium nuclei and free neutrons.

In the collapse of an iron core, the protons in the iron-like nuclei capture electrons and convert to neutrons. Each reaction creates a NEUTRINO. When the collapse reaches the density of atomic nuclei, the strong nuclear force has a repulsive component. The result of the increased pressure is that the collapse halts. A huge amount of energy is released when the neutron star forms. This energy is 1000 times more than is necessary to blow off the outer layers, those containing calcium, oxygen, carbon, and helium, and any outer envelope of hydrogen. The problem is that most of the energy produced in the collapse is lost to the neutrinos that can easily diffuse out of the newly born neutron star and stream through the infalling matter.

Uncertainties in the complex physics involved in core collapse have prevented an unambiguous understanding of the explosion mechanism. When the neutron star first forms, the new star overshoots its equilibrium configuration giving a large compression to the neutron

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

core. There is then a rebound. This rebound sends a strong supersonic shock wave back out through the infalling matter. The core takes about one second to collapse after instability sets in. The core bounce creates the shock in about one-hundredth of a second. The shock runs out into the infalling matter, however. Some of the energy of the shock is dissipated by the production and loss of neutrinos. The shock also must do the work of breaking down the infalling iron into lighter elements, protons and neutrons, to form the neutron star. The shock wave can thus stall with insufficient energy to reach the outer layers of the star. Matter can continue to rain down on the stalled shock front. The matter will still be shocked as material hits this front, but the shocked matter will continue to fall onto the neutron star. If enough matter lands on the neutron star, the neutron star will be crushed into a black hole. Current calculations show that the core bounce alone is not sufficient to cause an explosion.

One mechanism to create an explosion that is being actively considered takes advantage of the tremendous stream of neutrinos leaving the neutron star. Normal matter, the Sun, is essentially transparent to neutrinos since neutrinos interact only through the weak nuclear force. The only exception to this is neutron star matter. This matter, nearly as dense as an atomic nucleus, is so dense that it can be opaque or at least semi-transparent to the neutrinos. Although most of the neutrinos will get out into space, a small fraction will be trapped in the hot matter that lies just behind the shock front created by the core bounce even though this matter has a density that is much smaller than that of the neutron star. The accumulation of neutrino heat over a time of about one second may provide the pressure to re-invigorate the shock, driving the shock outward and causing the explosion.

The mechanism for depositing a small fraction of the neutrino energy behind the shock may be related to the boiling of the newly-formed neutron star. When the collapse is first halted and the neutron star rebounds, the neutron star is very hot. This heat can cause the neutron star to boil, much like a pan of water boils on the stove. The boiling provides a mechanism for carrying the heat outward in the case of the neutron star by mechanical motion. Under the right circumstances, this boiling process can be much more efficient in transporting heat than a slower process of leaking radiation, or neutrinos. Calculations of this process in neutron stars are very challenging because the motion is complex. All modern calculations that can follow motion in more than one (radial) dimension show that neutron stars do boil. There is a consensus that explosions will not occur without this boiling. There is still debate about whether this process is sufficient to cause an explosion.

Most of the current calculations of core bounce and subsequent events treat the configuration as spherically symmetric. Even if the neutron star boils, the structure of the neutron star may, on average, be spherically symmetric. There are a number of lines of evidence, however, that the explosions that result from the core collapse process are intrinsically non-spherical. Matter may be ejected more intensely in some directions than in others. If this is the case, then the current numerical calculations may be missing a major ingredient necessary to yield an explosion. The most obvious mechanisms for breaking the spherical symmetry are rotation and magnetic fields. Proper treatment of rotation and magnetic fields may be necessary to fully understand when and how collapse leads to explosions. Recent calculations have suggested that jets of matter associated with the rotation and magnetic field of the neutron star could play an important role in causing the explosion. This might alter the significance of the boiling neutron star and diminish the effect of the neutrinos.

White dwarf explosions

Type Ia supernovae are thought to explode in old, low-mass, long-lived stars. The observed properties of Type Ia are also remarkably uniform. Since white dwarfs of maximum mass, known as the Chandrasekhar mass, would be essentially identical and hence undergo nearly identical explosions, the observed homogeneity of Type Ia has pointed to an origin in exploding white dwarfs. We now know that all Type Ia supernovae are not exactly identical, but the basic principle still holds. The idea is then that the more massive star in an orbiting pair could evolve and form a white dwarf. The low-mass companion could then take a long time to evolve, but the companion would eventually transfer mass onto the white dwarf. If the total mass accumulated by the white dwarf approaches the Chandrasekhar mass of about 1.4 solar masses, the white dwarf will then explode.

Careful studies of the observed properties of Type Ia supernovae are completely consistent with the general picture that the explosion occurs in a white dwarf. The information revealed by the evolution of the spectra is consistent with a configuration in which the denser inner portions of the exploding star burn all the way to iron, but the outer parts are only partially burned. Computer models of exploding white dwarfs give results that match this pattern rather well. The exact nature of the combustion is still being explored, but the most successful models adopt a progenitor that is a carbon/oxygen white dwarf with a mass very near the Chandrasekhar mass.

There are two different ways of propagating a thermonuclear explosion in a white dwarf. One is a subsonic burning like a flame, a process called a deflagration. The other is a supersonic burning that is preceded by a shock front, much like a stick of dynamite. This process is known as a detonation. The most sophisticated current models, those that best match the data, have the unregulated carbon burning begin as a boiling, turbulent, deflagration and then make a transition to a supersonic detonation. Such models naturally create iron-like matter in the center and intermediate elements like magnesium, silicon, sulfur and calcium, on the outside. These models also predict that the white dwarf is completely destroyed, leaving no compact remnant like

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

a neutron star or a black hole. This comparison of theory and observation thus strongly points to an interpretation of Type Ia supernovae as the explosion of a carbon/oxygen white dwarf at the Chandrasekhar limit.

Type Ia progenitor evolution

Despite this convergence of opinion on the mechanism, there is no generally accepted picture of the evolutionary origin of Type Ia supernovae. The question of how the white dwarfs grow to the Chandrasekhar mass is still an unsolved problem. There is no direct evidence that Type Ia supernovae arise in binary systems. Despite this lack of direct evidence, all the circumstantial evidence points to evolution in DOUBLE STAR systems, and there are few credible ways of making a white dwarf explode without invoking a binary companion. The challenge is to figure out what binary evolution leads to a Type Ia explosion.

Type Ia supernovae are not all identical. The general trend is that Type Ia supernovae that are brighter than average decline from maximum brightness a bit slower than average. The events that are a bit dimmer than average (some by as much as a factor of 2!), decline more rapidly. Models of exploding Chandrasekhar mass white dwarfs can account for this behavior if the explosion in some stars makes the transition from a subsonic deflagration to a supersonic detonation a little earlier than in others. Why this should be so is the object of current research.

Light curves

Supernovae display a variety of shapes to their light curves. Type Ia supernovae are the brightest. They decay fairly rapidly in the first two weeks after peak light and then more slowly for months. Some Type II supernovae have an extended plateau and some drop rather quickly from maximum light. Both types seem to have a very slow decay at very late times, several months after the explosion. Type Ib and Ic supernovae are typically fainter than Type Ia by about a factor of two, but have similar shapes near peak light and show evidence for a slow decay at later times.

When a supernova first explodes, the matter is compact, dense and opaque. To reach maximum brightness, the ejected matter must expand until the material becomes more tenuous and semi-transparent. The size the ejecta must reach is typically 10 000 times the size of the Sun. This is 100 times the size of a red giant and 100 times the size of the Earth's orbit. As the matter expands, however, it cools. If the matter must expand too far before heat leaks out as radiation, the material may have cooled off so that there is no more heat to radiate.

Most Type II supernova explosions are thought to occur in red giant envelopes. These are very large structures. After the explosion, large envelopes do not have very far to expand before they become sufficiently transparent to leak their heat as light. As they begin to radiate, Type II supernovae still retain a large proportion of the heat that was deposited by the shock wave that accompanied the supernova. Near maximum light and on the typical plateau that lasts for months, Type II supernovae shine by the shock energy originally deposited in the star. The deposited energy presumably arises in the core collapse process.

For a Type I supernova, however, the story is different. Whether the exploding star is a white dwarf, as suspected for a Type Ia, or the bare core of a more massive star, as suspected for Type Ib and Ic, the exploding object is very small. The expected sizes range from one tenth to one thousandth of the size of the Sun. These bare cores are much smaller than the size to which they must expand before they can leak their shock energy. The result is that the expansion strongly cools the ejected matter and by the time the matter reaches the point where it could radiate the heat, the heat from the original shock is all gone. This kind of supernova requires another source of heat to shine at all. All the light from Type I supernovae comes from radioactive decay.

Radioactive decay

The nature of a thermonuclear explosion is to burn very rapidly. If the explosion starts with a fuel—carbon, oxygen, or silicon—that has equal numbers of protons and neutrons, then the immediate product of the burning will also have equal numbers of protons and neutrons. This is because the rapid burning takes place on the time scale of the strong nuclear reactions. To change the ratio of protons to neutrons requires the weak force and thus a longer time.

Iron is produced in a thermonuclear explosion in a three-step process. The first step is to produce an element that is close to iron, but that has equal numbers of protons and neutrons. This element, like iron, has a nucleus that is tightly bound by the nuclear force and has the same total number of protons plus neutrons, 56, but with 28 protons and 28 neutrons. This condition singles out one element, that with the most tightly bound nucleus containing equal numbers of protons and neutrons: nickel-56. Nickel-56 is, however, unstable and therefore undergoes radioactive decay. The radioactive decay is induced by the weak force. The result is the formation of the element cobalt-56. In the process, a neutrino is given off to balance the number of leptons. Excess energy comes off as gamma rays. The gamma rays can be stopped by collision with the matter being ejected from the supernova and their energy used to heat the matter. The hot matter then radiates. The power of the light falls off as the nickel decays away and as the matter expands so that it is less efficient in trapping the gamma rays. The cobalt-56 that forms is also unstable and decays to become iron-56. This decay again produces a neutrino and gamma-ray energy.

The radioactive decay of these elements is controlled by a quantum uncertainty. One does not know what atom will decay, but on the average half will decay in a given time. For nickel-56, the time for half to decay is 6.1 d. Likewise, the cobalt-56 decays with a half life of about 77 d. The observed light curves of Type I supernovae decay somewhat faster than the decay of nickel-56 in the

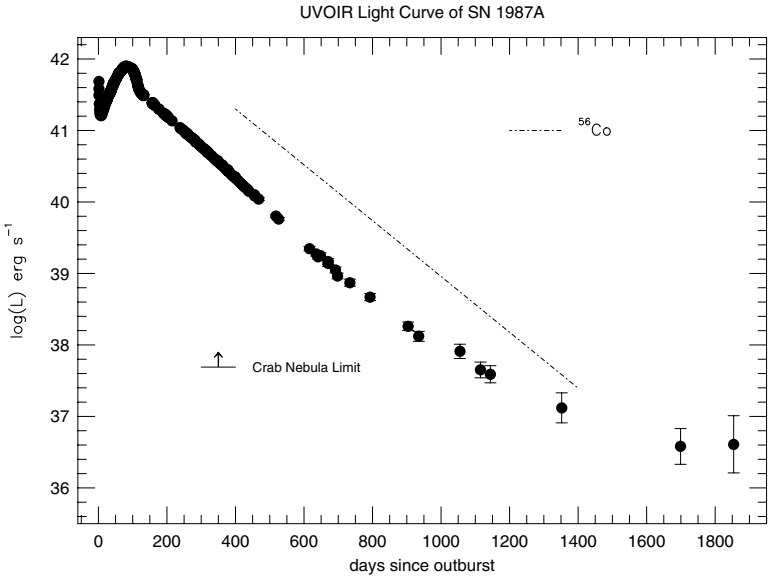

Figure 3. The light curve of Supernova 1987A in comparison with the expected slope for decay of radioactive cobalt-56 and the luminosity of the pulsar in the Crab Nebula. (Reprinted from *Astrophysical Quantities*, American Institute of Physics Press.)

early phase and of cobalt-56 in the later phases. The reason is that not all the gamma-rays produced in the decay are trapped and converted to heat and light. Some of the gamma rays escape directly into space.

For Type Ib and Ic, the amount of nickel required to power the light curve is about one-tenth of the mass of the Sun. This amount of nickel is consistent with many computations of iron core collapse. The nickel is produced when the shock wave impacts the layer of silicon surrounding the iron core. Similar reactions occur in Type II supernovae and similar amounts of nickel are ejected. Type Ia supernovae are generally brighter and must produce more nickel, of the order of 1/2 to 1 solar mass. The dimmest Type Ia events require only 0.1–0.2 solar masses of nickel. The models of Type Ia supernovae based on thermonuclear explosions in carbon/oxygen white dwarfs of the Chandrasekhar mass produce this amount of nickel rather naturally in the explosion. The amount can vary depending on, for instance, the density at which the explosion makes the transition from a deflagration to a detonation, so the variety of ejected nickel mass can also be understood, at least at a rudimentary level.

Supernova 1987A

Supernova 1987A was a Type II supernovae that occurred in the Large Magellanic Cloud about 150 000 light years from the Earth. This made it the closest and hence best studied supernova ever. Neutrinos were detected from SN 1987A, thus confirming the basic picture of core collapse. There was insufficient information to determine the precise mechanism of the explosion. The neutrinos mean that a neutron star formed, at least temporarily. No subsequent evidence for a neutron star has been detected (figure 3).

This may be because the neutron star is obscured in some way, or because it does not emit a normal flux of radiation. The latter could be because it is spinning rather slowly or has a rather small magnetic field. Another interesting possibility is that sufficient matter fell back onto the newly born neutron star to convert it to a black hole after the supernova shock was launched. SN 1987A also gave direct evidence for the production and decay of about 0.07 solar masses of nickel-56. The gamma-rays from the decay of cobalt-56 were directly detected. SN 1987A exploded as a rather compact blue supergiant rather than a red giant. The reasons for this are still not clear, but current reasoning suggests that the progenitor might have had a binary companion that was consumed when the progenitor became a red giant and engulfed the companion (figure 4). The relatively compact state meant that, unlike most Type II, SN 1987A was powered at maximum light by radioactive decay. SN 1987A is surrounded by a set of three nested rings of gas that were formed prior to the explosion. Their origin is unclear, but may be related to the binary interaction. The ejecta from the supernova is beginning to collide with the innermost ring. This interaction may yield more clues to the origin of this structure.

Supernovae and the universe

Because they are so bright, Type Ia supernovae have been used to determine distances. This information can be combined with the expansion velocity of the host galaxy to determine the HUBBLE CONSTANT and hence the age of the Universe. Subtle differences in the brightness for more distant supernovae have given evidence that the Universe is accelerating its expansion, contrary to expectation. The validity of this conclusion may rest on subtle differences

between nearby and distant supernovae that are under investigation.

A recent supernova, SN 1998bw, had characteristics of a Type Ic supernova but was excessively bright, asymmetric, had large expansion velocity, and produced one of the brightest radio sources ever associated with a supernova. There is also an indication that this supernova may have been associated with a gamma-ray burst observed on 25 April 1998.

Supersymmetry

A set of rules that attempts to link matter particles (fermions, such as quarks and leptons) and force-carrying particles (gauge bosons) into a single framework, or 'family'. Supersymmetry (abbreviation: SUSY), requires that each type of particle has a supersymmetric partner. For example, a photon (which is a boson) has a fermion counterpart (the photino), an electron (fermion) is partnered by a selectron (boson), a quark by a squark, and so on. The theory therefore predicts the existence of a wealth of hitherto unknown (and as yet undiscovered) particles. When the ideas of supersymmetry are applied to gravity, the resulting theory—supergravity—predicts the existence of one or more types of gravitinos (fermions) to partner the graviton (the hypothesized force-carrying particle for gravitation).

Surges

Surges are cool plasma jets ejected from small flare-like chromospheric bright points, such as subflares or Ellerman bombs (moustaches) near sunspots (see SOLAR CHROMOSPHERE: ELLERMAN BOMBS). They are a kind of active prominences, usually observed in Hα at ground-based observatories, although space observations (such as with EUV telescope) also detect surges. Figure 1 shows a typical example of an Hα surge observed at Hida observatory of Japan, revealing that the surge is emanating from an Hα bright point (subflare) in the periphery of the sunspot penumbra.

Kinematic properties and physical conditions

Surges are ejected at peak velocities of 50–200 km s^{-1} along a straight or slightly curved path, delineating magnetic field lines. They reach heights of 10 000–100 000 km and typically last 10–20 min. Many surges fall back into the chromosphere along the trajectory of their ascent, although some surges fall along the other half of the loop. Sometimes, small Hα brightenings are observed at the footpoint of surges in the falling phase. In some cases, a surge moves perpendicularly to the surge axis at a few tens of km s^{-1} during its ejection (this is referred to as whip-like motion in some literature).

There are some controversies on the kinematic properties of surge material. Some researchers reported that the motion of surges is not ballistic; surges are continuously accelerated during the ascent phase, while they are decelerated in the descent phase. However, some other researchers reported that surges show ballistic motion; all materials are accelerated in a short time and follow only the solar gravitational acceleration after that.

Some of surges show spinning motion at a few tens of km s^{-1} around their axis during the ejection phase. The direction of spinning motion is consistent with the direction of unwinding motion of their helical twist.

The electron density of surges is 10^{11}–10^{12} cm^{-3}, and their temperature is $\sim 10^4$ K. The total mass is 10^{13}–10^{15} g, and the kinetic energy ranges from 10^{27} to 10^{29} erg.

Surges have a strong tendency to recur at the same place at a rate >1 h^{-1}.

Magnetic field properties

The magnetic field strength at the footpoint of surges is of order of 50 G. The footpoint corresponds to small satellite spots (or satellite polarities) whose polarity is opposite to that of the main sunspot. Hence a neutral point or current sheet must be present at or near the footpoint of surges, suggesting the occurrence of magnetic reconnection there. Usually surges occur when magnetic flux is increasing or decreasing, i.e. in an evolving magnetic structure.

Many surges occur in emerging flux regions, especially in their early stage (see CHROMOSPHERE: EMERGING FLUX REGIONS). The typical shape of surges in emerging flux regions is an inverted Y-shape similar to the Eiffel tower (figure 2). This is consistent with the field configuration including a neutral point near the base of surges, which is expected for emerging flux reconnection model.

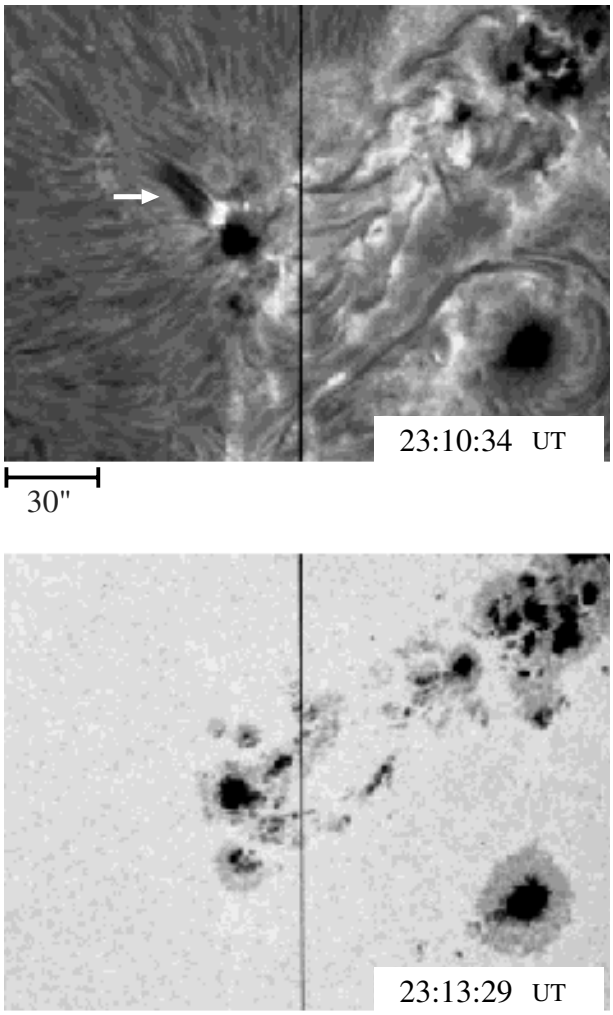

Figure 1. An Hα surge near a sunspot on the disk observed at Hida observatory (courtesy of S Sano). Top: H$\alpha \pm 0.0$ Å; bottom: H$\alpha - 5.0$ Å.

Relation to other phenomena

It is difficult to discriminate large surges whose velocity is more than 400 km s^{-1} from sprays, which are non-collimated cool plasma ejections expanding into large solid angles with velocity often larger than the Sun's escape velocity ($\sim$600 km s^{-1}). Sprays are usually associated with flares. Sometimes, they show an unwinding helical motion. The electron density and temperature of sprays are similar to those of surges. (The intermediate case between surges and sprays is shown in figure 3.)

On the other hand, small surges are similar to spicules, which are cool chromospheric jets observed in Hα and EUV at the network boundary (see CHROMOSPHERE: SPICULES). Their velocity and height are $\sim$30 km s^{-1} and 5000–8000 km, smaller than those of surges, while

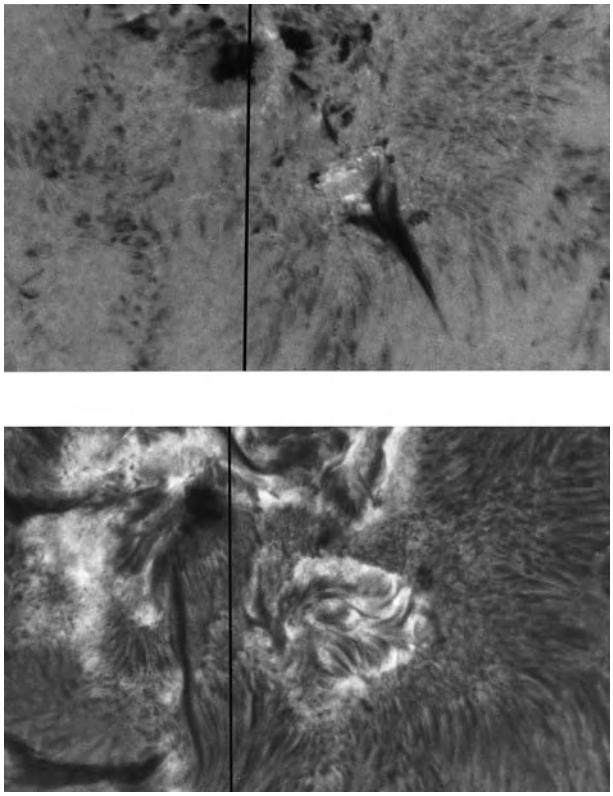

Figure 2. Top: An Hα surge in an emerging flux region, showing an inverted Y-shape similar to the Eiffel tower (observed at Hida observatory, courtesy of H Kurokawa) (03 UT 1 June; Hα − 0.8 Å). Bottom: Hα arch filament loops developing 20 h after the Hα surge shown in the top part (23 UT 1 June; Hα ± 0.0 Å).

Figure 3. An intermediate case between surges and sprays (observed at Hida observatory, courtesy of H Kurokawa).

their temperature and electron density are comparable with those of surges. Spicules show also a velocity feature suggesting spinning motion. It has not yet been established whether spicule motion is ballistic or not.

Macrospicules are observed in coronal holes and show characteristics between spicules and surges. They are ejected at ∼140 km s^{-1}, reaching heights of 10 000–35 000 km, and show nearly ballistic motion.

Flaring arches resemble surges. The only difference is that in flaring arches plasma is injected into a relatively small closed loop structure, whereas in surges the plasma injection goes along one arm of a loop or at some occasions along apparently open field lines. They consist of hot and cool plasmas, and thus can be seen in both Hα and x-rays.

Type III bursts are radio bursts, often occurring in association with surges (see SOLAR FLARES: RADIO BURSTS). These are emitted from high-energy electron beams propagating along open field lines, possibly the same or nearby field lines along which surges are ejected.

SOLAR X-RAY JETS are sometimes observed to be associated with Hα surges, nearly simultaneously and in nearly the same direction. There are also cases with no x-ray jet when Hα surges are observed. In such cases, x-ray bright points are often seen near the footpoint of Hα surges. The lack of x-ray jets may be because the density of hot jet is too low to be detected by soft x-ray telescopes.

EUV jets are jet-like features observed in EUV lines, first discovered by NRL HRTS experiments and later confirmed by SOHO SUMER/CDS/EIT. They are ejected at fast speed (∼400 km s^{-1}), extending to an altitude of 4000–16 000 km (but with a small width ∼1500 km), with mass of 3×10^{11} g and kinetic energy of $\sim 10^{26}$ erg. The relation between EUV jets and surges has not yet been made clear.

Table 1 summarizes characteristic physical quantities of various jet-like mass ejections in the solar atmosphere, including not only cool jets but also hot jets.

Formation mechanism

It is believed that the energy source of surges is magnetic energy stored in the solar atmosphere. In fact, the magnetic energy stored at the footpoint of surges (in a volume of 10^{27} cm^3 with a field strength of 50 G) is estimated to be $\sim 5 \times 10^{30}$ erg, which is enough to explain the observed kinetic energy of surges.

There is increasing observational evidence for magnetic reconnection in surges, such as association with satellite polarities, the inverted Y-shape (or Eiffel tower shape), whip-like motion which is interpreted as a sling-shot-like motion as a result of reconnection, and so on.

Table 1. Various jet-like mass ejections in the solar atmosphere.

Mass ejections	Velocity (km s^{-1})	Length (km)	Mass (g)	Kinetic energy (erg)	Temperature (K)
Spicules	30	(5–8) × 10^3	10^{11}–10^{12}	10^{24}–10^{25}	(0.5–1) × 10^4
Macrospicules	∼140	(1–4) × 10^4	10^{12}–10^{13}	10^{26}–10^{27}	10^4
Surges	50–200	(1–10) × 10^4	10^{13}–10^{15}	10^{27}–10^{29}	10^4
Sprays	>200	>10^5	10^{14}–10^{15}	10^{29}–10^{30}	10^4–10^5
EUV jets	400	(0.4–1.6) × 10^4	3 × 10^{11}	10^{26}	10^5
X-ray jets	10–1000	10^4–3 × 10^5	10^{11}–10^{13}	10^{25}–10^{27}	(3–7) × 10^6
X-ray plasmoids	50–400	>10^5	10^{13}–10^{14}	10^{27}–10^{28}	(5–16) × 10^6

Even spinning motion can be interpreted as a result of reconnection between a twisted flux tube and an untwisted flux tube (see figure 4). Hence it is very likely that magnetic reconnection is a key mechanism to produce surges.

What is the collimation mechanism of surges? It is easy to show that magnetic force can collimate surges; the gas pressure of surges is 0.1–1.0 dyn cm^{-2} while their magnetic pressure is 100 dyn cm^{-2} for 50 G, much larger than the gas pressure.

Even if magnetic reconnection is a key to the production of surges, there remains a fundamental question: what is the specific acceleration mechanism of surges? Namely, is a surge accelerated by gas pressure force enhanced by a sudden release of magnetic energy or is it accelerated by magnetic force as a result of reconnection? Hence, there are basically two accelerating forces: one is the gas pressure and the other is the magnetic force ($\boldsymbol{J} \times \boldsymbol{B}$ force).

Gas pressure force

If a sudden energy release occurs in the upper chromosphere, the gas pressure increases and directly accelerates cool plasmas in the upper chromosphere along an open flux tube.

If an explosion occurs in the photosphere or in the low chromosphere, the hydrodynamic shock wave (slow-mode MHD shock) propagates along an open flux tube through the chromosphere to accelerate cool plasmas in the upper chromosphere.

In both cases, the speed of the gas-pressure-driven jet is basically determined by the sound speed (i.e. temperature) in the high-pressure region or shock-heated region, and is written as

$$V_{jet,gas\text{-}p} \sim 3C_s \simeq 150\left(\frac{T}{10^5\ \mathrm{K}}\right)^{1/2}\ \mathrm{km\ s^{-1}} \qquad (1)$$

where C_s and T are the sound speed and temperature of the high-pressure (or shock heated) regions, respectively. (This velocity is a maximum speed when the high-pressure gas expands into vacuum.)

Magnetic force

If a magnetic field line reconnects with another field line, magnetic tension force is generated in the reconnected field line as in a sling-shot. Such a magnetic tension force accelerates plasmas on the reconnected field line up to the Alfvén speed just outside of the current sheet. (See figure 5 for a magnetic reconnection model of a surge, which shows that not only cool jet but also hot jet are ejected from reconnection region.)

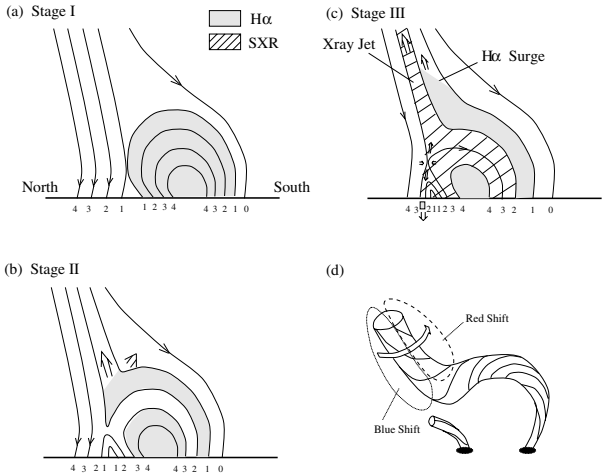

Figure 4. A magnetic twist model for Hα surges (Canfield *et al* 1996 *Astrophys. J.* **464** 1016; see also Shibata and Uchida 1986 *Sol. Phys.* **103** 299).

If a plasmoid (confined by a magnetic island) is created in a current sheet as a result of reconnection and if there is a gradient of magnetic field strength in the ambient field along the current sheet, the plasmoid would be accelerated by the magnetic pressure gradient in the ambient magnetic field. This is known as the diamagnetic mechanism or melon seed mechanism.

If a twisted flux tube reconnects with an untwisted flux tube, magnetic twist would be suddenly released into the untwisted flux tube. During this process, a magnetic pressure gradient force appears along the reconnected flux tube and accelerates the plasma contained in the reconnected flux tube. If the reconnected flux tube has a diverging cross-sectional area, a centrifugal force would also act as an additional accelerating force.

In either case, the velocity of magnetically driven jets

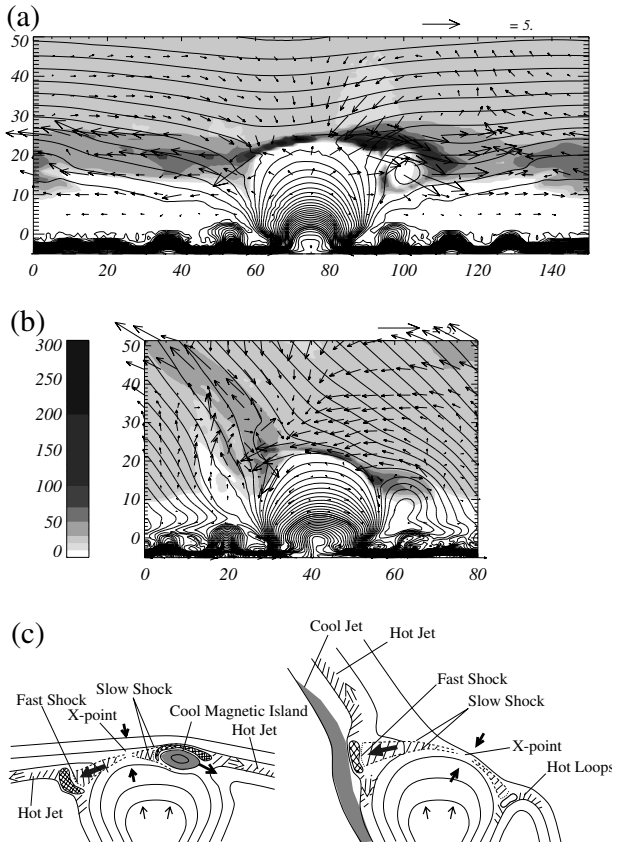

Figure 5. Illustration of emerging flux reconnection model of a surge (Yokoyama and Shibata 1996 *Publ. Astron. Soc. Japan* **48** 353).

is of the order of the Alfvén speed;

$$V_{jet,mag} \sim V_A \simeq 300 \frac{B}{30\ \mathrm{G}} \left(\frac{n}{10^{11}\ \mathrm{cm}^{-3}} \right)^{-1/2} \mathrm{km\ s}^{-1}. \quad (2)$$

Here B is the magnetic flux density and n is the electron density.

Generally speaking, if jets are cool enough, it is difficult to accelerate such cool jets by gas pressure without raising the temperature, whereas it is quite easy to accelerate cool jets by magnetic force while keeping a low temperature. Hence the magnetically driven jet mechanism has wider applicability as a model for cool jets. This is especially true for larger jets (such as large surges and sprays), although, as for smaller jets (such as spicules and small surges), there still remains the possibility that jets are accelerated by gas pressure force or slow-mode MHD shock.

To elucidate the acceleration mechanism of various jet-like phenomena in the solar atmosphere (table 1) would be a challenging subject for the future. Such study is also useful for the study of astrophysical jets ejected from active galactic nuclei, close binary systems and young stellar objects.

Surveyor

Series of seven NASA automated Moon landers, launched 1966–68. Designed to send back images and other data on potential APOLLO landing sites near the lunar equator. Surveyor 1 was the first spacecraft to make a controlled soft landing on another world. Surveyors 5–7 carried out *in situ* soil analyses. Surveyor 6 performed the first lift-off from the lunar surface. Surveyors 2 and 4 were failures. Parts of surveyor 3 were returned to Earth by Apollo 12 astronauts.

Swedish Space Corporation (SSC)

Located in Solna, near Stockholm. SSC is a government-owned commercial company with activities covering space systems engineering, space operations and the commercial exploitation of space. SSC also offers support and technical expertise to the National Swedish Space Board.

It has two establishments at Kiruna in the Arctic—the Esrange satellite operations facility and sounding rocket range, and Satellitenbild, a subsidiary devoted to processing of remote sensing data.

The corporation provides scientific instruments and oversees launches of stratospheric balloons and sounding rockets with astronomical and microgravity payloads. It also builds small satellites and had overall responsibility for the Viking and Freja scientific satellites.

Symbiotic Stars

During the production of the Henry Draper Catalog, Wilhemina Fleming identified several M-type stars with unusually strong hydrogen emission lines. Paul Merrill obtained higher quality spectra of these 'stars with combination spectra' and found intense emission from He II or [O III] and [Ne III] in addition to H I. All of these stars varied by 0.5–1 mag on a timescale of several years. A few systems underwent occasional 2–3 mag eruptions, where a much hotter continuum overwhelmed the red giant spectrum. Louis Berman and Frank Scott Hogg suggested that these objects must be double stars. Merrill, Otto Struve and Pol Swings later confirmed this picture with the detection of periodic radial velocity variations. Merrill suggested 'symbiotic stars' to describe this small class with 'two objects of quite different kinds . . . living close together in extraordinary interdependence and adjustment'.

Phenomena

The modern definition of a symbiotic star relies on spectroscopic criteria outlined by Merrill and Cecilia Payne-Gaposchkin. These are (figure 1)

(1) a red continuum and absorption features, of a late-type giant star (spectral type K or M); and
(2) a blue continuum with bright H I and He I emission lines and either
(a) additional high ionization emission lines, for example He II, [Ne V], and [Fe VII], with an equivalent width exceeding 1 Å (quiescent objects and some eruptive systems), or
(b) an A- or F-type continuum with additional absorption lines from H I, He I, and singly ionized metals (systems in outburst). The absorption features often have P Cygni emission components.

The sample of ∼150 known systems includes two dozen established in the 1930–1950s and others selected from recent spectroscopic surveys. The lack of a systematic survey precludes a proper estimate of the symbiotic frequency. Current estimates suggest there are 3000 to 300 000 in the Milky Way. Most systems lie close to the galactic plane or in the bulge; some are halo stars. A handful are in the Magellanic Clouds; at least one resides in the Draco dwarf spheroidal galaxy.

All quiescent symbiotics are small-amplitude VARIABLE STARS. Most vary by 0.5–1 mag on a timescale of 1–2 yr. Some systems *flicker* by 0.01–0.1 mag on minute timescales; a few show periodic optical and x-ray pulsations with 10–30 min periods. The amplitudes of the flickering and of the pulsations increase toward decreasing wavelength. Roughly 20% contain MIRA variables with pulsation periods of 300–500 d. The pulsation amplitudes increase from 0.5–1 mag at infrared wavelengths to 1–4 mag in the optical.

Symbiotic stars undergo complicated outbursts. Figure 2 shows optical light curves for the recurrent nova T CrB, the classical symbiotic CI Cyg, and the *symbiotic nova* AG Peg. In T CrB, the rise to visual maximum occurs in less than one day. The fast decline suggests rapid ejection of material as in fast classical NOVAE. The eruptions of classical symbiotics are slower, with a rise time of weeks to months and a decline over several orbital cycles. Symbiotic nova outbursts take decades or centuries. AG Peg began an eruption *c*. 1850 and is slowly approaching minimum.

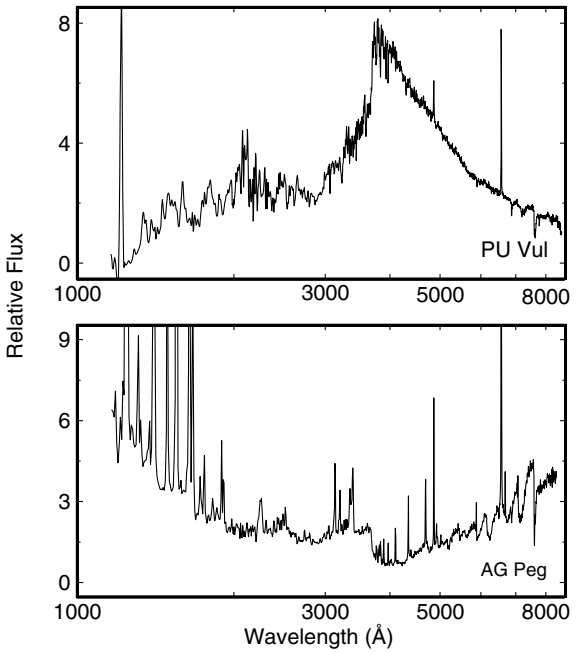

Figure 1. Spectra of symbiotic stars in quiescence (AG Peg; lower curve) and outburst (PU Vul; upper curve). In quiescence, the spectrum contains a strong hot continuum rising towards short wavelengths, strong emission lines and a prominent Balmer jump from the nebula, and a red continuum from the red giant. The hot component often evolves into an F-type supergiant with weak emission lines during eruptions. This spectrum overwhelms the red giant except at the longest wavelengths.

Despite different timescales, the spectroscopic evolution throughout outburst is remarkably similar. In recurrent novae, most classical symbiotics, and many symbiotic novae, an A or F-type continuum overwhelms the red giant spectrum at visual maximum (see figure 1). Many strong emission lines weaken considerably as the brightness increases and strengthen as the brightness fades. The H I and He I lines develop into strong absorption features often with P Cygni profiles. In symbiotic novae and some classical symbiotic stars, the ejection velocity increases from ∼100–200 km s^{-1} at visual maximum to ∼1000–2000 km s^{-1} during the decline. The velocity remains large, ∼2000–3000 km s^{-1}, throughout a recurrent nova eruption. Small velocities, 100–200 km s^{-1}, are characteristic of eruptions in CI Cyg and other classical symbiotics.

Many Mira symbiotics undergo less dramatic symbiotic nova eruptions. Despite a similar 3–5 mag optical rise, the systems never develop A- or F-type optical spectra. High ionization emission lines remain strong. Low

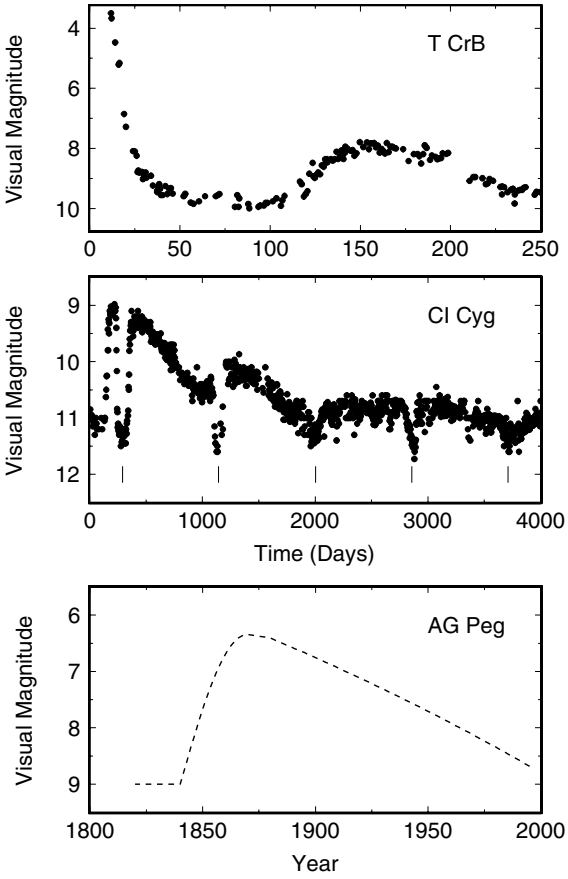

Figure 2. Outburst light curves of three symbiotic stars (adapted from Kenyon (1986)). The recurrent nova T CrB rises 6 mag to optical maximum in less than one day, declines to minimum in ∼50 d, and then rises to a secondary maximum 4–5 mag below primary maximum. CI Cyg, a classical symbiotic, rises 2 mag in several weeks and returns to minimum in 5–10 yr. The vertical tick marks indicate eclipses of the hot component by the giant. The symbiotic nova eruption of AG Peg began before 1850; the system took ∼20 yr to reach maximum and is slowly returning to minimum.

velocity mass ejection is not apparent at visual maximum; broad emission features similar to those in WOLF–RAYET stars appear several years after optical maximum. Several classical symbiotic stars sustain similar 'weak' eruptions and may eject mass at low velocities, ∼100–200 km s^{-1}.

These and other phenomena support Berman and Hogg's original notion that symbiotics are BINARY STARS. Two stars, red giant and 'hot component', account for the two continua with color temperatures of ∼3000 K and ≥50 000 K (figure 1). Energetic photons from the hot component ionize a surrounding nebula. Many well-studied systems show good evidence for orbital motion with periods of 1–3 yr. System masses are ∼1–4 $M_\odot$. The brightness fluctuations are often phased with the orbit and can be explained by (i) illumination of the red giant atmosphere by high-energy photons from the hot component, (ii) eclipses of the hot component and a surrounding nebula by the red giant, or (iii) ellipsoidal variations of the tidally distorted red giant. These interpretations provide further support for the binary picture and allow for detailed studies of the stars and the nebula.

Hot component

The nature of the hot component remained elusive until the 1970s, when satellite ultraviolet observations revealed a hot continuum to accompany the high ionization optical emission lines. These data show that the quiescent luminosity of the hot component is comparable to the red giant luminosity. The effective temperature must exceed ∼50 000 K to explain He II emission. Thus, the hot component has a small radius, ∼0.1 $R_\odot$ for a luminosity of ∼100 $L_\odot$. The dynamical timescale for this radius, ∼300–500 s for a stellar mass of 0.5–1 $M_\odot$, is consistent with the flickering timescale. The escape velocity, ∼1000 km s^{-1}, is close to the maximum ejection velocity observed in most systems.

Despite this simple order-of-magnitude consistency, the hot component cannot *maintain* its large luminosity for the lifetime of the RED GIANT STAR. The $\sim 10^5$ yr cooling time for a 0.6 $M_\odot$ WHITE DWARF with a luminosity of 100 $L_\odot$ is 1% of the lifetime of its red giant companion. Both of these timescales are short compared to the $\gtrsim 10^9$ yr main sequence lifetime of either star. The probability of finding a hot white dwarf in a binary with a red giant is thus small. Perhaps 1–2% of symbiotics are produced in this way. The main alternative to such 'accidental' symbiotics is an interacting binary, where the hot component accretes material lost by the red giant. Generating ∼100 $L_\odot$ from gravitational infall requires accretion rates of $\sim 10^{-5}$ $M_\odot$ yr^{-1} onto a main sequence star and $\sim 10^{-7}$ $M_\odot$ yr^{-1} onto a white dwarf star. White dwarfs can burn the accreted material in a thin hydrogen shell above the white dwarf core, which reduces the needed infall rate to $\lesssim 10^{-8}$ $M_\odot$ yr^{-1}.

Detailed studies of individual symbiotic systems suggest three different types of hot components. Quiescent symbiotics with UV continua that rise towards short wavelengths, as in figure 1, contain hot white dwarfs with radii of ∼0.1 $R_\odot$ and temperatures that range from ∼30 000 K up to 200 000 K. The white dwarfs masses, 0.5–1 $M_\odot$, are similar to single white dwarfs. The flat UV spectra observed in roughly 10% of known symbiotics are better explained with emission from a disk having a temperature that decreases from ∼20 000 K at the inner edge to less than 5000 K at the outer edge. Radiation from the boundary layer—a $\sim 10^5$ K region where material at the inner edge of the disk slows to the rotational velocity of the central main sequence star—ionizes the nebula. Finally, two symbiotics are hard x-ray sources and contain accreting NEUTRON STARS. One of these, V2116 Oph, has a very high ionization optical spectrum and displays interesting x-ray variations. Little is known about the other neutron star symbiotic, HD 154791.

Cool component

The structure of the cool component is best inferred from near-IR observations. These data separate symbiotics into two broad classes. *S-type* symbiotics contain G-, K- or M-type stars with color temperatures, $T_c \approx$ 2500–4500 K at 1–3 μm wavelengths. These red giants have strong near-infrared CO absorption bands and modest emission from circumstellar dust at 10–100 μm. Some vary on a timescale of 100+ d with 0.1–0.3 mag amplitudes at 1–3 μm. This amplitude often increases towards shorter wavelengths; radiation from the hot component masks this behavior in some systems. *D-type* symbiotics have smaller color temperatures, $T_c \approx$ 1000–1500 K, strong near-infrared H_2O absorption, and significant mid-infrared dust emission. Most D types also contain Mira variables that are several times more luminous than the red giants in S-type systems. The cooler, dusty photosphere must then have a factor of $\sim$10 larger radius than the radius of an S-type red giant. To contain such a large Mira variable within its tidal radius, the orbital periods of D-type systems should be 10–100 times longer than orbital periods for S-type symbiotics. All S-type symbiotics have short orbital periods, $\leq$3 yr. Reliable orbital periods for D types are rare, but most estimates range from decades to centuries.

Understanding mass loss from the cool component relies on optical, near-IR and radio observations. Several symbiotics have red giants that fill their Roche lobes and lose mass tidally at high rates. Most symbiotic red giants underfill their Roche lobes by factors of 2–10 and can only lose mass via a stellar wind. Two sets of measurements indicate high mass loss rates for these red giants. Radio spectral energy distributions at 1–20 cm allow estimates of the mass, radius, and outflow velocity of the ionized nebula in $\sim$50 symbiotics. Combining this information yields mass loss rates of $\sim 10^{-6}\ M_\odot\ \mathrm{yr}^{-1}$. Emission lines produced in the optically thin, outer atmosphere of the red giant require similar mass loss rates. The gravitational range of the hot component suggests that it can accrete roughly 1% of the mass lost by the red giant wind. This amount is sufficient to power the hot component providing a hydrogen shell burns the accreted material. The large mass loss rates estimated for the red giants in symbiotics exceed mass loss rates of single red giants with identical physical properties by 1–2 orders of magnitude. The origin of the high mass loss rates is uncertain.

Nebula

Despite the similarities of their hot stars, symbiotic nebulae have little in common with PLANETARY NEBULAE. Prominent forbidden lines and intense radio emission indicate smaller, denser nebulae in symbiotics, with densities of 10^5–10^6 cm^{-3} and sizes of 1–100 AU. Strong intercombination emission suggests densities exceeding $\sim 10^8$ cm^{-3} on scales of 1 AU or less in all S-type systems. These lines are rare in D types.

Photoionization produces most of the emission from symbiotic nebulae. Observations over several orbital cycles indicate a stratified nebula with density decreasing outwards from each component. Rapid eclipses indicate that high ionization lines—e.g. He II and N V—form in high-density material near the hot component. Slower occultations of lower ionization emission suggests formation in high-density material near the cool component. Several very high ionization features are produced by photoionization and scattering: Raman scattering of O VI $\lambda\lambda$1032,1038 emission lines off H I atoms in the red giant wind produces broad 6830 Å and 7088 Å emission bands. Understanding this process has led to direct measurement of the orbital inclination in several systems.

The wind from the hot component is often energetic enough to interact with the wind from the cool component. The shock front produced by these 'colliding' winds can produce observable amounts of thermal x-ray and high ionization line emission if the kinetic energy in the winds is large. A typical 1 $L_\odot$ x-ray luminosity requires a mass loss rate of $\sim 10^{-8}\ M_\odot\ \mathrm{yr}^{-1}$ from the hot component for an ejection velocity of 1000 km s^{-1}. In a few cases, the interaction is in the form of jets. First proposed to explain the variable velocity of [O III] emission in AG Peg, deep images of several D-type symbiotics show narrow jets of H I emission similar to those observed in planetary nebulae and some pre-main-sequence stars. The origin and frequency of this emission is unknown.

Models for symbiotic stars

Figure 3 shows simple schematics of typical symbiotic binary stars. The top panel shows a semi-detached system where the lobe-filling red giant transfers material into a large disk around a main sequence star. Radiation from the disk and boundary layer power the UV continuum and ionize the nebula. Ionized material surrounds the disk and one hemisphere of the red giant; neutral gas lies behind the red giant as viewed from the disk. The dynamics and ionization structure of the nebula are poorly known. Whether or not the disk ejects material into the ionized nebula is also uncertain. By analogy with dwarf novae, outbursts in these semi-detached symbiotics occur either when an unstable red giant increases the mass transfer rate into the disk or when an unstable disk increases the mass transfer rate onto the central star. Models and observations are currently insufficient to ascertain which of these two possibilities causes the outburst of any semi-detached symbiotic.

The middle panel shows the most common type of detached symbiotic where a white dwarf or neutron star accretes material from the wind of a normal red giant. Some material lost by the giant falls into a disk surrounding the white dwarf. The dynamics of the red giant wind and the material accreted onto the white dwarf are poorly understood. The accretion rate is high enough to support nuclear burning on the white dwarf, which produces a hot ultraviolet source that ionizes most of the red giant wind. The most luminous hot components eject material that interacts with the red giant wind. This interaction produces a bow shock around the red giant, as

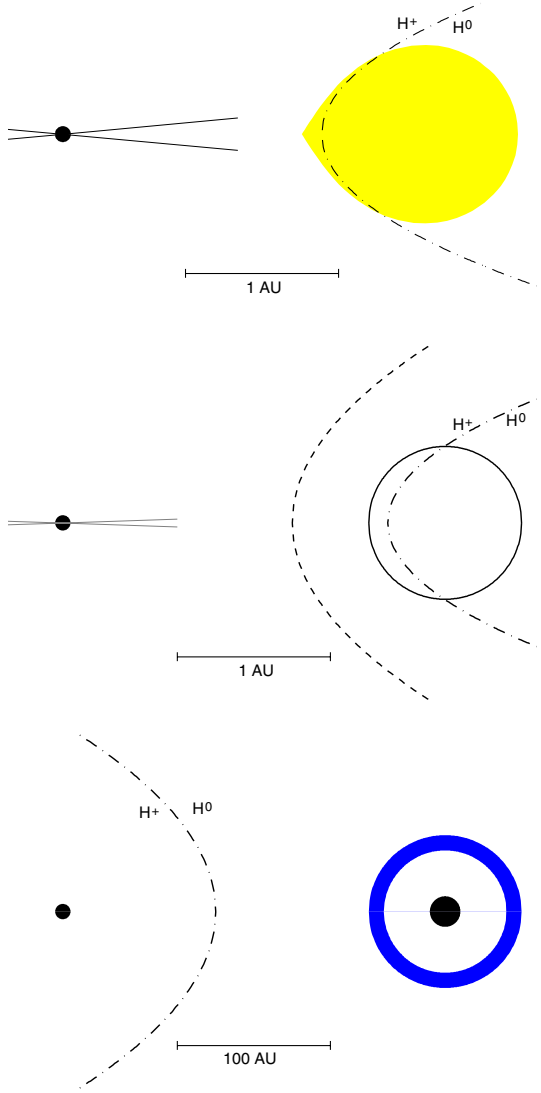

Figure 3. Schematic orbital configurations for three types of symbiotic stars. In each schematic, the red giant component is on the right and the hot component is on the left. The hot component is surrounded by a disk (shown from the side for simplicity). A length scale in AU is included with each panel. Regions of ionized hydrogen (H^+) and neutral hydrogen (H^0) are marked accordingly. The dashed line in the middle panel shows the general region where a wind from the hot star may interact with material lost by the cool star.

indicated by the dashed line between the hot component and the red giant. The dynamics of this region and how it affects the accretion flow are also poorly understood.

The bottom panel shows the geometry of a Mira symbiotic. The large mass loss rate from the Mira allows dust condensation in the wind. Dust condenses well outside the Mira photosphere, as indicated by the ring surrounding the red giant in the figure. This dust is often thick enough to obscure the Mira at optical and near-infrared wavelengths. The geometry and dynamics of material in the dust shell is not known. Despite the very wide orbital separation, the hot component accretes enough material from the wind to power an ultraviolet continuum and bright emission lines. The hot component often cannot ionize a large fraction of the Mira wind, so the ionization front curves around the hot component instead of around the red giant as in other symbiotics.

The outbursts of the two classes of detached symbiotics are usually interpreted as thermonuclear runaways in the hydrogen burning shells of white dwarf stars. This explanation accounts for the slow eruptions of symbiotic novae such as AG Peg. It fails for the rapid eruptions of recurrent novae and classical symbiotics unless the white dwarf is close to the Chandrasekhar limit. There is good evidence for a massive white dwarf in T CrB, but most symbiotics have hot components with masses of $\lesssim 1\ M_\odot$. Disk instabilities are a possible alternative to thermonuclear runaways but have not been studied in much detail.

In the past decade, symbiotic stars have generated renewed interest as possible progenitors of type I SUPERNOVAE. The small white dwarf masses in symbiotics make a carbon detonation supernova unlikely. In some accreting white dwarfs, however, hydrogen burning may produce a massive helium shell that can undergo a different type of supernova. Learning how to distinguish supernovae in a symbiotic binary from other types of supernovae remains an unsolved problem. There is also great uncertainty about the importance of the symbiotic contribution to the observed frequency of type I supernovae, due to the unknown frequency of symbiotic stars in the Milky Way and other galaxies and to the uncertain outcome of the helium shell explosion. Resolving these unknowns may allow Merrill's stars with combination spectra to contribute to the measurement of cosmological parameters such as H_0 and q_0.

Synchronous Orbit

An orbit in which the period of revolution of an orbiting body is the same as the rotation period of the body it is orbiting. In the solar system, the only natural instance of a synchronous orbit is that of Pluto's satellite, Charon. Some artificial satellites are put into synchronous orbit around the Earth; such orbits are then termed *geosynchronous*. If in addition such an orbit is circular and in the Earth's equatorial plane, it is termed *geostationary*, since from a point on the Earth's surface a satellite in such an orbit appears to keep approximately the same position in the sky. Geosynchronous and geostationary orbits are used for navigation and communications satellites.

Synchronous Rotation

The rotation on its axis of a celestial object in the same time as it takes to orbit another object, also called *captured rotation*. In other words, the orbiting body's rotation and revolution periods are identical. Synchronous rotation results from tidal forces between the two bodies. Most of the major satellites in the solar system, the Moon included, have synchronous rotation and always keep the same face turned toward their parent planet. In the Moon's case libration means that in the course of time rather more than 50% of the Moon's surface is visible from the Earth. Pluto's satellite Charon is unique in having both synchronous rotation and a synchronous orbit: its period of revolution, and the rotation periods of both planet and satellite, are identical. From either body, the other is motionless in the sky. Synchronous rotation can also occur in binary stars with near-circular orbits.

Synchrotron Radiation

Radiation emitted by electrons moving at very high speeds (approaching the speed of light) in magnetic fields. An electron follows a helical path around a magnetic field line and, at relativistic (i.e. close to the speed of light) velocities, emits radiation in a narrow cone in the direction of its motion. Synchrotron radiation has a characteristic spectrum and generally exhibits a high degree of polarization. The synchrotron process is an important source of radiation from astronomical sources. For example, around the planet Jupiter high-energy electrons spiraling through the lines of force of the planet's magnetic field give off synchrotron radiation at radio wavelengths. In the Crab Nebula synchrotron radiation at such wavelengths and at those of visible and ultraviolet light is generated by electrons moving in the magnetic field associated with the supernova remnant. Also radio emissions of the synchrotron variety have been detected from other supernova remnants in our Galaxy and from extragalactic objects such as radio galaxies and quasars.

Synodic Period

The time interval between two successive similar alignments of two celestial bodies. In the case of a planet, the synodic period may be taken to be the mean time interval between, say, two successive oppositions or two successive conjunctions. It is this period that determines the times at which particular planets will be visible in the night sky. The Moon's synodic period is the time between successive recurrences of the same phase; such as between full moon and full moon.

Synthetic Stellar Populations

Modern telescopes are built with ever-better angular resolution, but for galaxies and clusters outside the local group we generally cannot hope to study the stars in them one by one. Instead, we see the sum of the light from all of the stars. To take this integrated starlight and extract information on the ages or heavy-element abundances requires a model; a synthetic version of how many and what kind of stars are present. To guide the models, we rely on nearby stars and star clusters where stars can be studied one by one and also on theoretical models of stellar evolution and stellar atmospheres.

A STELLAR POPULATION is a group of stars born at the same time and sharing the same initial composition. A STAR CLUSTER is an example of a simple stellar population, characterized by a single age and a single abundance mixture. The MILKY WAY is an example of a complicated mixture of many stellar populations; old and young, metal poor and metal rich.

In the Milky Way, there is a striking concordance of age–metallicity with spatial extent and kinematics. The GALACTIC METAL-POOR HALO is thought to have formed in the first third of the Galaxy's history and is composed of stars and clusters on randomly oriented orbits so that the net effect is a large halo of roughly spherical shape. On the other hand, if one finds all the stars in the Galaxy younger than a billion years, virtually all of them are in the very thin Galactic disk. They have orderly, near-circular orbits with all stars rotating clockwise as seen from above the Galactic north pole (see GALACTIC THIN DISK). This dichotomy gave rise to the notion of two distinct stellar populations in the Milky Way around 1944 (W Baade is credited with this idea). By the 1960s it became evident that there were several, rather than two, distinct populations. For instance, old but metal-rich stars exist both in the disk and in the bulge. Today, we have given up counting the number of stellar populations, and instead speak of the age and abundance distributions within kinematic subgroups.

From distant galaxies and clusters, what information can one hope to derive from integrated star light? Ultimately, one could hope to find the complete star formation history of the galaxy, and at each past epoch of star formation the population's dynamic state, a distribution of heavy elements, and an initial mass function (abbreviated IMF; the number of stars born at each mass). Such a detailed picture is out of reach for the present. Today, we have clues about each of these quantities, but we are far from being able to wrestle such a detailed picture from integrated light observations.

Several types of synthetic stellar population models

Figure 1 shows galaxy spectra covering the range of spectral shapes that are seen along with a sampling of some of the stellar types out of which the galaxies are composed. From the figure one can glimpse similarities between the galaxies and the underlying stellar types.

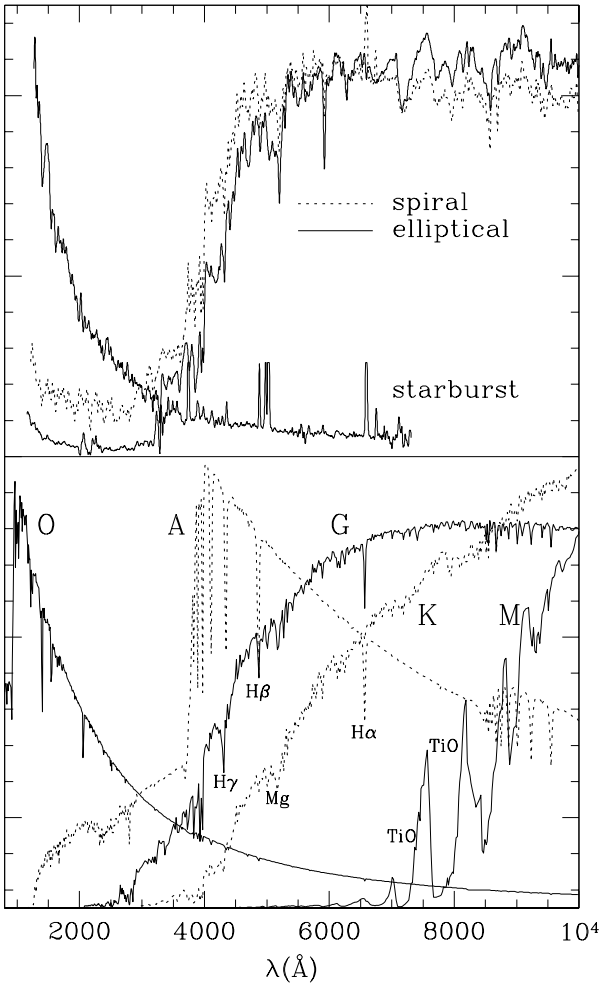

Figure 1. Example galaxy (top) and star (bottom) spectra are shown, arbitrarily scaled F_ν versus wavelength in Å. The strongest emission lines in the starburst spectrum were truncated for clarity, and a few important spectral features are marked on the stellar spectra. This is the synthesis problem: adding the star spectra together in different combinations and with different multiplicative weights, how closely can the galaxy spectrum be matched? By eye, one can see that the starburst galaxy must have a strong O star component, and the spiral and elliptical galaxies must have many G stars. However, TiO features appear in the spiral and elliptical spectra, so KM stars must also be present.

Extreme STARBURST GALAXIES emit most of their light in the ultraviolet. Their spectra are matched by OB-type stars with strongly muted evidence of other spectral types. SPIRAL and ELLIPTICAL GALAXIES have minority populations of hot stars, as seen by their small ultraviolet fluxes, and obviously have a strong G-star component. However, the strong, broad TiO features characteristic of M-type stars are seen in the red portion of the spectrum, so very cool stars are present as well.

The first type of model is this kind of star-by-star

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

addition problem. Early workers such as Spinrad and Taylor would observe, spectrophotometrically, a collection of stars and a few galaxies. Then, by method of trial and error, they would construct a 'model' consisting of the relative proportions of the stars that best matched the galaxy spectrum. That is, given a galaxy spectrum L_λ and a collection of stellar spectra $l_{i,\lambda}$, the model consists of the weights w_i by which the stars are multiplied:

$$L_\lambda = \sum_i w_i l_{i,\lambda}. \quad (1)$$

The trial-and-error part comes in because the same set of weights must work for all λ. A useful improvement came with the work of Faber in the early 1970s. Through a careful statement of the problem and judicious use of technique (quadratic programming or linear programming) the trial-and-error portion of assigning weights was replaced by numerical optimization.

This form of population modeling is often termed empirical population synthesis. Empirical population synthesis has a couple of drawbacks. First, solutions are not unique. For instance, the spectrum of a G dwarf closely resembles that of a G giant, and replacement of one by the other probably will not noticeably affect the goodness of fit. Second, information on galaxy age or metal abundance requires interpretation. Suppose the synthesis says that G0 dwarfs are numerous, but F8 dwarfs are rare. The interpretation would be that the main sequence turnoff is at spectral type G0. One would then refer to observed star clusters or stellar evolutionary isochrones to find out the age at which the main sequence turnoff is spectral type G0.

The connection to age and metal abundance can be made more direct by considering, not stars, but star clusters as the basic building block. The cluster will already have the 'correct' proportions of the different kinds of stars for the cluster's age and abundance, and finding the best match between target (galaxy) and template cluster should, in principle, yield a mean age and metal abundance for the galaxy. In practice, two problems arise. First, in the Milky Way and vicinity, open clusters are so diffuse that obtaining an integrated spectrum is observationally impossible. One is then left with the globular clusters and the clusters in the LMC and SMC for possible spectral templates. E Bica has made a study of such cluster spectra. While these clusters span a considerable range of age and abundance, not all possibilities are covered. In particular, the high metallicities typical of elliptical galaxies cannot be matched by local template clusters. The second problem is age–metallicity degeneracy, which is the observation that changes in age and metal abundance have very similar, almost indistinguishable, effects on the integrated spectrum, so that an old, metal-poor population may very closely resemble a young, metal-rich population. This topic is revisited below.

The final variant of model was developed by B M Tinsley starting in the late 1960s and today is the most widely used variant. It is usually referred to as evolutionary population synthesis or isochrone synthesis because it uses theoretical stellar evolutionary isochrones as its basic unit rather than observed clusters. A stellar evolutionary isochrone (isochrone for short) is made from a collection of evolutionary tracks for different masses of stars. A track describes the luminosity and effective temperature of a star of a given mass with time. An isochrone shows the locus of luminosities and temperatures at one instant in time for stars of all masses, and thus is built to mimic a star cluster or a single-age stellar population.

Sample isochrones together with some terminology

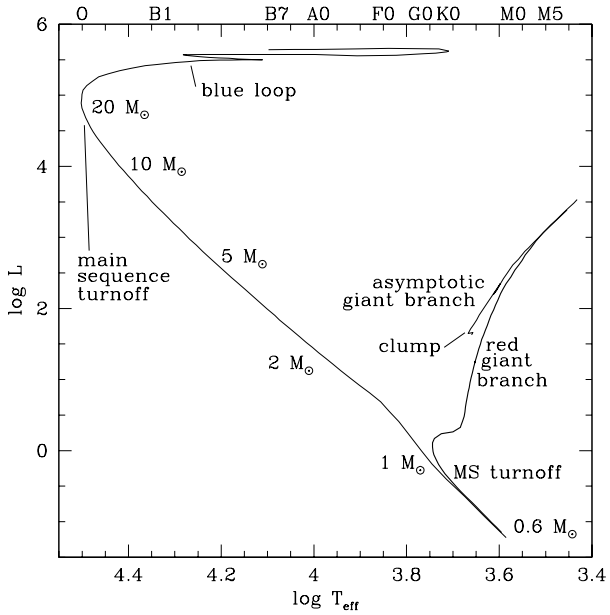

Figure 2. Isochrone age effects are shown. The isochrones plotted are for solar composition, ages 5 million and 15 billion years. Approximate spectral type is indicated on the top axis, and log $T_{\rm eff}$(in kelvins) on the bottom. The vertical scale is the logarithm of the bolometric (total) luminosity in units of the solar luminosity. The masses of main sequence stars are marked. The 'main sequence turnoff' is the point where the isochrone drifts brighter than the zero-age main sequence. Stars in this phase often dominate the integrated light and are also crucial for age estimation. Post-main-sequence evolution happens on much quicker timescales than main sequence lifetimes. Massive stars undergo 'blue loops' in response to internal structural changes, and may also spend some time as M-type supergiants before they explode in supernovae explosions. Low-mass stars have entirely different post-main-sequence evolution. They evolve up a 'red giant branch' as they fuse hydrogen in a shell around the helium core. At log $L \approx 3.4$, the helium reaches ignition temperature and the star immediately adjusts its structure to land in the 'clump'. In a metal-poor population, the clump may spread over a large range of temperature, and in this case is called the 'horizontal branch'. After the clump, the star climbs the asymptotic giant branch (AGB) before shedding its outer layers, undergoing a planetary nebula phase, and finally becoming a white dwarf.

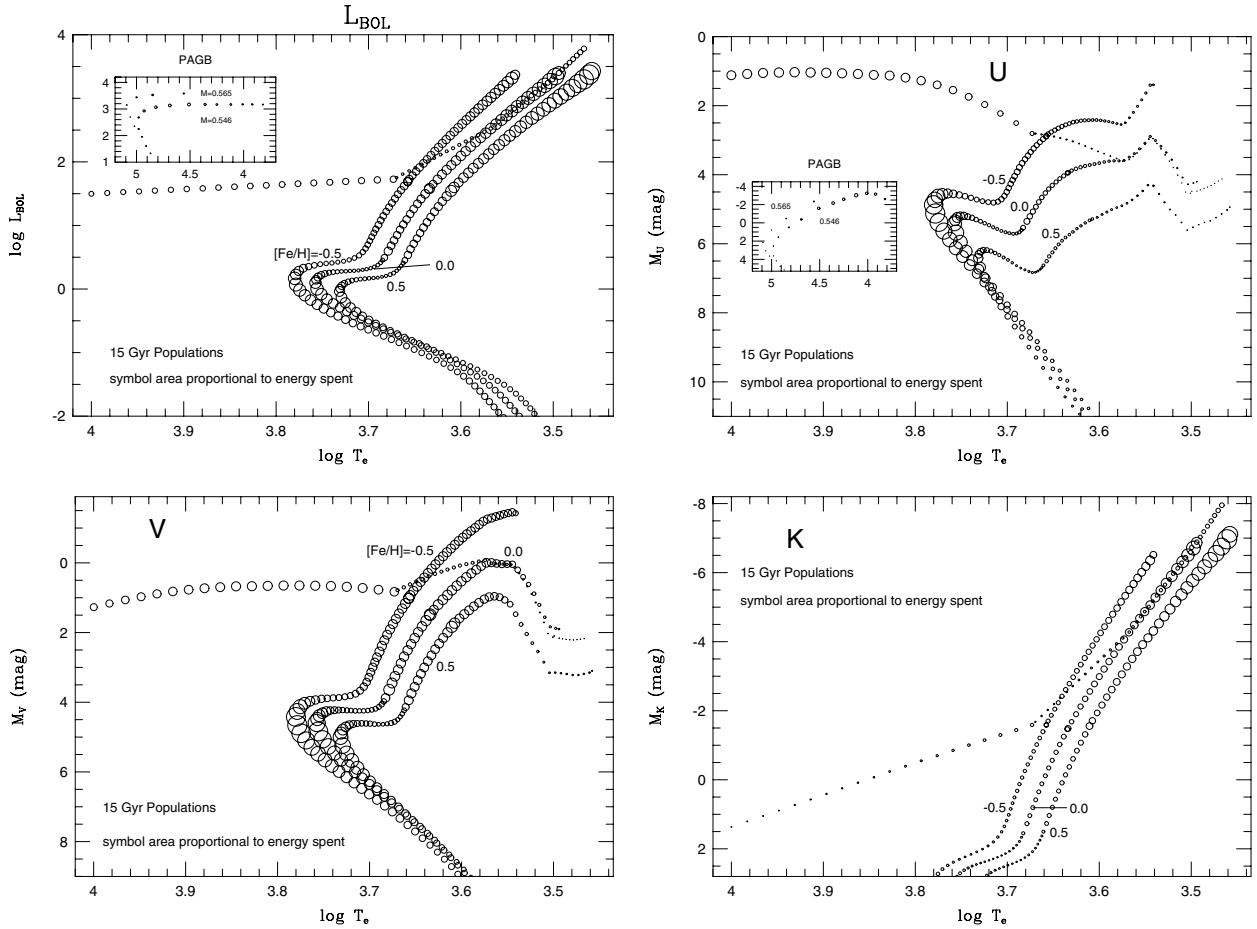

Figure 3. The four panels in this figure give a visual impression of which phases of evolution dominate the integrated light at different wavelengths. Isochrones of 15 billion year age are shown for [Fe/H] = −0.5, 0.0 and 0.5 dex. The effect of changing the abundance is to shift the isochrones in temperature. The [Fe/H] = 0.0 isochrone has a 'horizontal branch', an 'asymptotic giant branch' and a 'post-asymptotic giant branch' (marked PAGB) showing evolution in and around the planetary nebula phase for two postulated white dwarf masses. For clarity, these late stages are not illustrated for the other two isochrones. The horizontal branch is included for illustration purposes only; the usual morphology of this phase for a metal-rich population is a clump. Each bin along the isochrone is represented by a circle, which changes size according to how much energy is spent at that location. Therefore, most of the light comes from where the largest circles are located. The four panels show bolometric (all-wavelength) light in which the light contributions are split between main sequence turnoff and giant branch, the ultraviolet U filter in which only the warmer stars contribute, the visual V filter which resembles the bolometric panel and the infrared K filter in which the brightest giants, all but invisible in the other panels, completely dominate the light.

are shown in figure 2. There are two essential points about isochrones. First, more massive stars have much shorter main sequence lifetimes, so the main sequence turnoff point will move steadily dimmer and cooler with increasing age. Second, the post-main-sequence phases of evolution are much shorter than the main sequence lifetimes. In most situations stars near the main sequence turnoff region will dominate the integrated light. One case where this is not true is for an old population where one is restricted to looking in the red or infrared. In that case, the cool red giant stars dominate the light. The isochrones in figure 2 are of SOLAR ABUNDANCE, but model builders also consider other abundances. We use the standard bracket notation [Fe/H] or [M/H] to mean the logarithmic heavy-element abundance in units of the solar heavy-element abundance:

$$[\mathrm{Fe/H}] = \log[n(\mathrm{Fe})/n(\mathrm{H})]_{\mathrm{stars}} - \log[n(\mathrm{Fe})/n(\mathrm{H})]_{\odot}. \quad (2)$$

In addition to the isochrone, a collection of stellar spectra is required. These spectra can be empirical, theoretical or any combination. The spectra may even consist solely of broad-band colors, if that is the only information desired of the model at the end. The final model spectrum is a weighted sum of the stellar spectra mathematically identical to equation (1):

$$L_\lambda = \sum_i N_i(M, \delta M) l_\lambda(T_{\mathrm{eff}}, g, Z) \quad (3)$$

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

where L_λ is the model spectrum, i is the index over points along the isochrone, $N_i(M, \delta M)$ is the number of stars associated with each point along the isochrone, and $l_\lambda(T_{\rm eff}, g, Z)$ is the stellar spectrum, which is typically interpolated from a grid of star fluxes indexed by effective temperature, surface gravity and abundance. The number of stars comes from the IMF, which gives the number of stars per interval of mass. A simple power-law IMF is still in common use today, for example

$$N_i(M, \delta M) = CM^{-x}\delta M \tag{4}$$

where C is a constant and $x = 2.35$ is the 1955 Salpeter estimate. Masses for each isochrone point are tabulated in the isochrones together with temperature and luminosity.

Examples of how the addition goes are shown in figure 3, in which isochrones are plotted point by point. The sizes of the points are varied so that the area of each is proportional to $N \times l$, the total luminosity coming from that isochrone point. Therefore, one can obtain a visual impression of what evolutionary phases are important by looking for the larger symbols. In total energy output ($L_{\rm bol}$) it is evident that the bright red giants are dominant, with main sequence turnoff stars secondary. In the U filter, the giants contribute almost nothing, with the main sequence turnoff stars dominant. The horizontal branch, if present, is a significant source of light. In the V filter stars of many different kinds contribute, but in the near-infrared K filter nothing but the brightest KM giants contribute significantly. For populations younger than about half a billion years, the giant branch does not develop as illustrated, and the main sequence stars are more important.

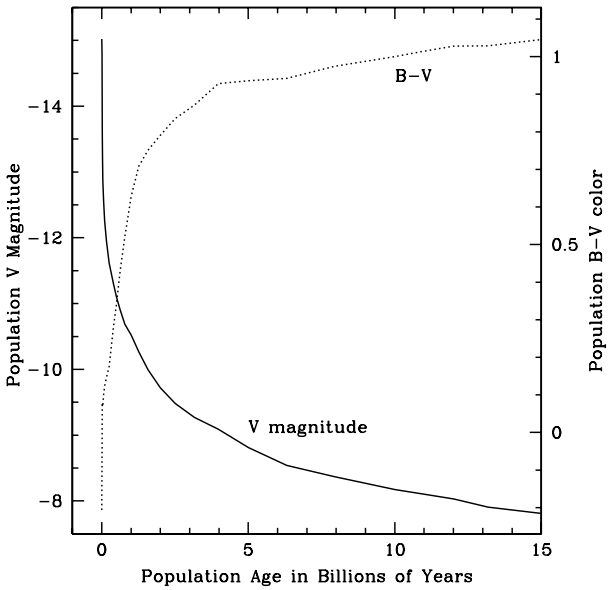

Figure 4. Population fading in the V band is shown as a function of age. The V magnitude of a population of $10^6 M_\odot$ is shown by the solid curve, and the left-hand axis gives the scale. Color reddening is also shown where $B - V$ color is shown by the dotted curve and the right-hand axis gives the scale.

Synthesis model behavior and uncertainties

The basic behavior of a stellar population is (1) the population becomes dimmer with age, (2) the population becomes dimmer with increasing abundance in passbands bluer than about 1 μm, brighter in passbands redder than that, (3) the population becomes redder with age or increasing abundance and (4) neutral metallic lines increase in strength and, after about 10^8 yr, hydrogen Balmer lines decrease in strength with increasing age or abundance. The age caveat in point (4) arises because the hot OB stars present in very young populations have relatively weak Balmer lines, and when those stars dominate the Balmer lines fade somewhat. The Balmer lines peak in strength for turnoff stars at about A0 spectral type ($\sim 7 \times 10^8$ yr isochrone age) and fade for cooler stars. Metal lines increase monotonically with decreasing star temperature. The behavior is shown in figure 4, which shows dimming of a population in the V band, and reddening of the $B - V$ color.

The rate of dimming with age is controlled by the IMF, which controls how many stars exist at each mass. If there are relatively more massive stars in a population, it will be brighter when young. The IMF does not strongly affect the color evolution and is almost negligible in its effects after a substantial red giant branch develops, a bit shy of a billion years of age. This is because almost all the light comes from stars near the main sequence turnoff or from post-main-sequence stars. All of these stars have nearly the same mass (because post-main-sequence lifetimes are relatively short) so there is little mass differential for the IMF to work on.

Since we do not know how much the IMF varies from environment to environment there is corresponding uncertainty in the synthesis models. This is an astrophysical uncertainty, but there are technical uncertainties as well since most of the ingredients in an isochrone synthesis model are suspect at some level. The isochrones themselves appear to be the dominant source of error. Stellar lifetimes and luminosities are somewhat uncertain, but the temperatures predicted by the isochrones are the most critical component and one of the hardest to obtain accurately. Temperature errors lead directly to errors in derived ages and abundances. The stellar flux libraries have problems also. Theoretical fluxes do not match real stars, especially in the ultraviolet and infrared where the atomic and molecular line lists are incomplete. Observed libraries have observational error, limited wavelength coverage, uncertain flux calibration and often inappropriate resolution. The combined effect of these technical problems is estimated to render derived ages uncertain by about 35% for populations older than a billion years. The uncertainty is larger for younger populations.

There are sometimes problems in the observational material that make it difficult to apply a model based solely on star light. Dust may be present in the observed galaxy,

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

possibly with a variety of geometries. This will affect colors owing to scattering and absorption of starlight. If stars are currently forming in a galaxy, nebular emission lines from H II regions are present. Together with other species, the hydrogen Balmer lines are present in emission, filling in the stellar absorption lines. This can make the Balmer absorptions, which are important age diagnostics, very hard or impossible to measure.

Another significant hurdle for all types of population models is age–metallicity degeneracy, in which age effects look similar to metallicity effects in integrated light. To illustrate the problem figure 5 shows isochrones and fluxes for a trio of populations. The 5 billion year old, $[\mathrm{Fe/H}] = -0.1$ dex population is the reference population. The second population is three times older than the reference, the third twice as metal rich, but their spectra fall virtually on top of one another. The null-change slope is approximately $\Delta \log(\mathrm{age}) = (-3/2)\Delta \log Z$.

Is age hopelessly intertwined with abundance? Fortunately, it is not. A careful look at the model spectra reveals several features that do not participate in the $-3/2$ slope. Some metallic absorption features are relatively more sensitive to metals. Hydrogen Balmer lines track the main sequence turnoff temperature closely without much regard for the giant branch temperature and hence are relatively age sensitive. Ultraviolet-to-red colors behave the same way (but in practice are hampered by the presence of a minority of hot horizontal branch or post-AGB stars and by dust, if present). The presence of luminous red AGB stars has been proposed as another age indicator, since the AGB is observed to be very strong in clusters less than about 2 billion years of age, but the stellar evolutionary details of this are difficult to work out. Additional age indicators are being sought by today's researchers. For the moment, it appears that arraying a Balmer feature against a sensitive metal feature is the most reliable way to estimate simultaneously a mean age and a mean metal abundance. Example diagnostic diagrams are shown in figure 6.

Another astrophysical uncertainty is the mixture of elements that are used for the 'abundance'. A scaled-solar abundance pattern seems to apply approximately throughout the local disk, but metal-poor halo stars have light elements that are more abundant relative to Fe-peak elements. A similar abundance pattern applies in the GALACTIC BULGE and also in large elliptical galaxies (see below). The impact of changing the heavy-element ratios is primarily on the temperature structure of the isochrone and the appearance of the stellar spectra, with secondary effects on stellar lifetimes and luminosities. However, the modeling that is required to calibrate these changes is only now starting to be carried out, so the ultimate impact of differing elemental mixtures is difficult to estimate. As it stands now, the local template stars have spectra which differ in line strength pattern from the spectra of some galaxies and clusters, so a perfect model-to-galaxy match is not possible.

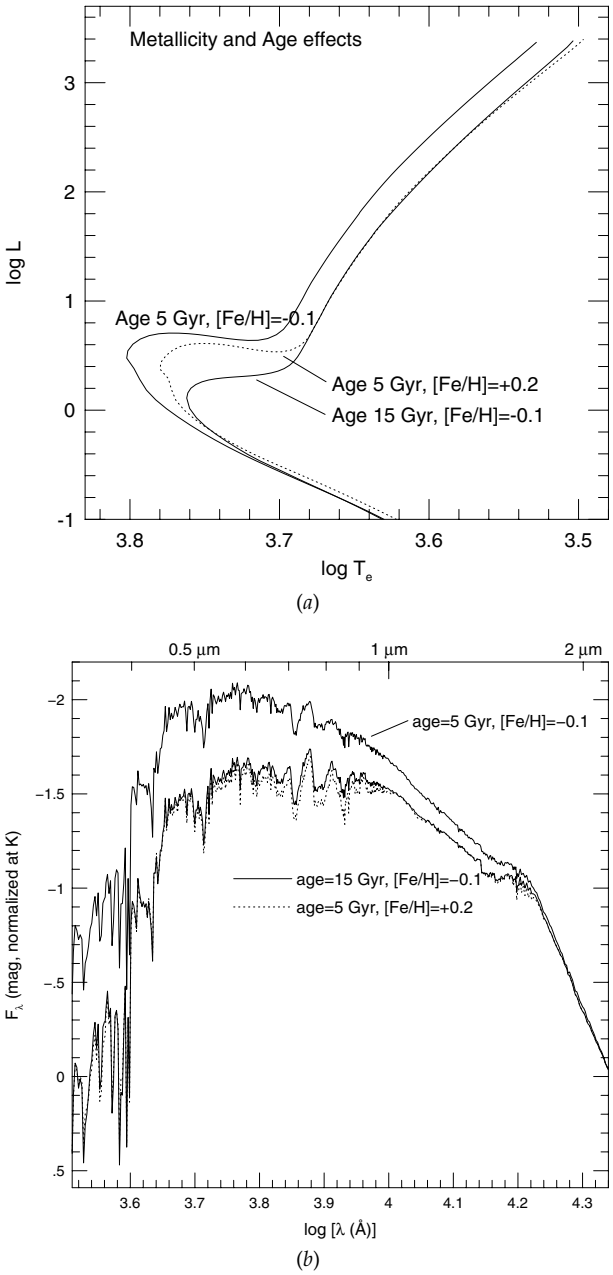

Figure 5. (*a*) Matched isochrones and (*b*) model spectra that illustrate age–metal degeneracy are shown. The base population is age 5 billion years, with slightly less than solar metallicity. Of the other two populations, one has age tripled, the other has metallicity doubled. Despite differing in abundance by a factor of 2 and differing in age by a factor of 3 both spectra lie nearly on top of one another.

A final astrophysical uncertainty is the difficulty of composite populations, systems that are composed of many different ages and abundances. In particular, there is a strong masking effect when a young population is present together with an underlying old population.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

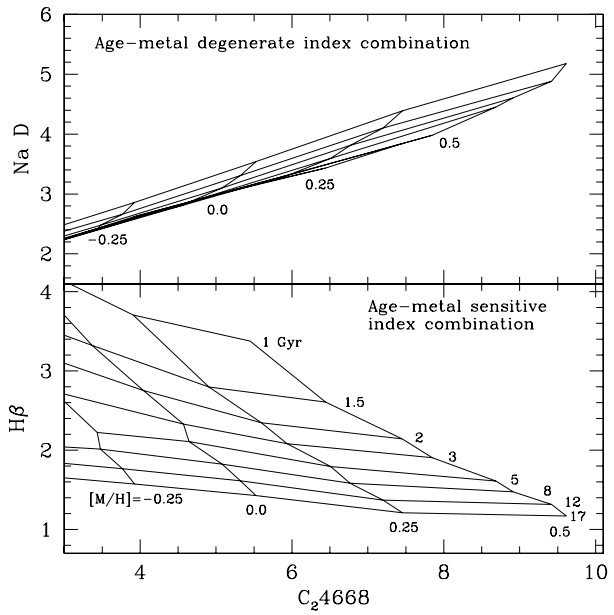

Figure 6. While most index–index diagrams are age–metal degenerate, as in the top panel showing an Na D index versus an index measuring mostly molecular carbon, some show fairly good ability to separate the two effects, as in the bottom panel showing Hβ. Note that an 'index' could be a color, an absorption feature index or even an SBF magnitude. The choice of indices presented here is arbitrary. Metallicity values and ages in billions of years are marked on the grid lines that represent simple-population models.

Since young populations are very much brighter, they will dominate the integrated light even when the young population represents only a few per cent of the total mass. When 'mean ages' are derived for galaxies, the youngest population present gets far more weight than the older ones.

Applications of synthesis models

Over the years we have learned a great deal about distant GLOBULAR CLUSTERS and galaxies from the study of their integrated starlight as interpreted through synthesis models. The following examples illustrate some of the ways that this class of models has been applied.

Globular cluster systems are attractive targets because all but the very largest of them appear to be not only co-eval but also monometallic so that they can be characterized by a model of a single age and metal abundance. The first globular cluster system to be studied was the Milky Way's. Direct stellar abundance estimates are available for these nearby systems, so the strong connection between integrated color (or metal line strength) and abundance is obvious. The Milky Way globular clusters are believed to have formed at various times during the first third of the Galaxy's life so they are uniformly ancient. They remain crucial benchmarks for testing synthesis models.

Colors of globular clusters around other galaxies are now becoming available out to ∼8000 km s^{-1} and low-resolution spectra can be obtained out to ∼1500 km s^{-1} with 8 m telescopes. Clusters around elliptical galaxies are the most common target. Metal abundance can be derived by assuming old ages and using synthesis models to go from observed color to abundance. Note that the −3/2 age–metal slope works in our favor when metal abundance is sought: a 30% age uncertainty corresponds to a 20% abundance uncertainty, which is less than 0.1 dex. The typical globular cluster system has both metal-poor and metal-rich clusters, some of which have apparently greater than solar abundance. The Milky Way is missing the metal-rich component seen in most other galaxies. The metal-rich component often appears as a separate hump in the abundance histogram and is seen to be more centrally concentrated than the metal-poor clusters.

Elliptical galaxies show a color–magnitude relation in which brighter galaxies are redder. Since it is unlikely that smaller galaxies are all younger than their larger brethren, and since synthesis models predict reddening with increasing abundance, a higher abundance in the larger ellipticals is inferred.

Mean ages of early-type galaxies without emission lines can be estimated from Balmer absorption strength arrayed against metallic feature strengths. The results for local galaxies show a strong clump of old-appearing ages, with a significant trail of galaxies toward young ages. This indicates a degree of star formation activity inconsistent with a universal primordial formation for all elliptical and S0 galaxies.

Light/heavy element ratios in elliptical galaxies are not constant. When absorption features rather than colors are examined, Fe or Ca features are nearly constant regardless of galaxy size, but features sensitive to Mg, Na and N abundance are stronger in larger galaxies. This was discovered when synthesis models were compared with absorption line data. On the positive side, this tells us much about the types of SUPERNOVAE responsible for the chemical enrichment in galaxies of different sizes. On the negative side, this introduces more parameters to be encompassed by the synthesis models, increasing uncertainty.

Surface brightness fluctuations are pixel-to-pixel variations about the mean brightness of an image of a galaxy due to almost-resolved stars. The further away a galaxy is, the smoother its appearance because more stars fit into each pixel, suppressing the 'noise'. Tonry and Schechter quantified this phenomenon and exploited it as a distance indicator with potentially excellent accuracy. The size of the observed surface brightness fluctuations depends only on galaxy distance and the luminosity function of the brighter stars present in the galaxy (see also LUMINOSITY FUNCTION OF GALAXIES). The luminosity function can be predicted from population models, which show a slope with color and predict an absolute zero point for the distance scale.

Post-starburst objects can be reliably found with variations on the technique of using Balmer lines in conjunction with features more sensitive to abundance. Large numbers of galaxies that look quiescent but in fact have had a large burst of star formation in the recent past have been discovered in nearby GALAXY CLUSTERS, supporting a view in which galaxy clusters are in the midst of forming even today.

Cosmological studies of GALAXIES AT HIGH REDSHIFT almost always require evolutionary synthesis models to interpret the observed magnitudes and colors. The Doppler shift moves the spectrum to longer wavelengths, affecting the colors. Furthermore, at large look-back times the stars seen will be younger than their local counterparts, and therefore brighter and bluer. The synthesis models allow an accounting of these effects.

Starburst galaxies are bravely examined, despite dust and nebular emission, with the hope of deriving a high-mass IMF, among other things. The key observables are the C IV and Si IV resonance lines in the vacuum ultraviolet. Massive stars have winds that generate P Cygni profiles in these lines. More massive stars have faster and denser winds, generating stronger P Cygni profiles with larger blueshift. This technique offers a sensitive IMF test for stars with $M > 30M_{\odot}$. To date, the evidence suggests that the IMF looks about the same in distant STARBURST GALAXIES as it does in local group star forming regions.

The G dwarf problem is the observation that the solar neighborhood is deficient in stars of abundance less than 1/10th of solar abundance compared with the simple closed-box model of chemical evolution. Synthesis models have been used to estimate the metal-poor population fraction present in early-type galaxies by looking at the amount of main sequence turnoff light contributed in the near-UV and at spectral features sensitive to the presence of A-type metal-poor horizontal branch stars. The conclusion is that the G dwarf problem is universal. Other galaxies, even the nuclei of elliptical galaxies, do not contain as many metal-poor stars as the simple model predicts.

Chemo-dynamical models attempt to start with a cloud of gas and numerically turn it into a galaxy, with correct dynamics and chemistry along the way. These complex computer models can also include a population synthesis portion so that the surface brightnesses and colors of the model galaxies can be simulated as well. Today's models are approximate and underconstrained, but this is a promising avenue for future work.

Syrtis Major

A prominent dark, triangular albedo feature (dark by contrast with its surroundings) on the Martian equator, centered approximately at 10 °N, 70 °E. It takes its name from the historical name for the larger of two quicksands off the North African coast. Syrtis Major is prominent in telescopic views of the planet, and was in fact the first feature of Mars ever to be recorded, in a sketch made by Christiaan Huygens in 1659. It continued to be recorded by observers of Mars, and appears on various maps made during the nineteenth century, including those drawn by Nathaniel Green and Eugène Antoniadi. When spacecraft mapped the planet in the 1970s very few of the classical albedo features were found to correspond to topographical features. Syrtis Major is one of the exceptions, coinciding with a volcanic plateau centered at 9.5 °N, 70.4 °E. The plateau, which bears the official name Syrtis Major Planum (changed in 1982 from Syrtis Major Planitia), is a flat, lightly cratered area that slopes gently down toward Isidis Planitia to the east. A low-relief shield volcano on the plateau is probably responsible for the dark material that covers the region; winds shift this material around, causing changes in the appearance of Syrtis Major as seen from Earth and creating dune fields. In the southwest lies a prominent crater, 456 km in diameter, appropriately named Huygens, while in the northwest lies another large crater, the 381 km diameter Antoniadi.

T Tauri Stars

The T Tauri stars are the most well known class of pre-main sequence stars. They are low- to intermediate-mass stars with ages of typically a few million years. At this stage in their evolution, the newly collapsed stars have become optically visible but are still surrounded by gas and dust from their formation, typically in a disk. In the HR diagram, they are located where one expects contracting, fully convective pre-main sequence stars to fall. Observationally they appear as cool, luminous stars that exhibit emission lines, excess infrared and ultraviolet continuum flux, variability and are sometimes associated with jets, molecular outflows, winds, accretion or x-ray emission. Studies of the T Tauri stars help provide insight into the formation of the Sun and solar system.

Tarantula Nebula (NGC 2070)

An emission nebula in the Large Magellanic Cloud, in the constellation Doradus, position RA $05^{h}\,39^{m}$, dec. $-69^{\circ}\,07'$. At half a degree across, it is far larger than any emission nebula visible in our Galaxy. It is energized by several young hot O and B type stars, the brightest of which is designated R136. The Tarantula gets it name from its spidery appearance.

Tarde, Jean (1561/2–1636)

French parish priest, geographer and astronomer, born in La Roque-Gajac, near Sarlat, France, adopted Copernicanism and set up an observatory to view sunspots, which he thought were satellites of the Sun. He named them 'Bourbon stars', in the same manner that GALILEO had named the satellites of Jupiter the Medician stars.

Tartu Observatory

Tartu Observatory (TO) is a research institution in Estonia accommodating the northernmost 1.5 m telescope in the world. It is located in Estonia, about 20 km southwest of Tartu in the village of Tõravere (58°16′08″.4 N, 26°27′32″.4 E). TO performs research in astrophysics and atmospheric physics and popularizes those branches of science. TO was founded in 1808 as an observatory of Tartu University and it gained worldwide renown under the leadership of F G W Struve (1793–1864, director of the Observatory 1820–39). In 1824 TO was equipped with a 9 in (23 cm) Fraunhofer telescope which was the world's largest refractor. TO was working as the Observatory of the University until World War II. In 1946 the Observatory was transferred to the Estonian Academy of Sciences. In 1958 building works at a new observing site (Tõravere) were begun, and in 1964 the new observatory was opened. Between 1947 and 1995 the observatory had various different names. Since 1995 the official name has been Tartu Observatory and it is subordinated directly to the Estonian Ministry of Education.

The staff in 1999 was 64, of whom 38 were research associates.

Major observing facilities include the 1.5 m telescope (installed in 1975) equipped with a Cassegrain spectrograph, and the 0.6 m telescope (installed in 1998) with a CCD photometer.

The research can be divided into four main projects: formation and evolution of galaxies in the expanding universe; structure and evolution of stars and stellar atmospheres; climate forming factors and dynamical weather forecast for Estonia; and the radiation regime of the atmosphere and ground surface and optical monitoring of the Estonian environment.

TO is supported mostly from the state budget of Estonia. Minor additional finances are obtained from a few international projects and contracts with Estonian organizations.

Tata Institute of Fundamental Research

The Tata Institute of Fundamental Research, Department of Astronomy and Astrophysics has over 20 scientists carrying out research in theoretical astrophysics, optical and near-infrared astronomy and space astronomy (far-infrared, x-ray and gamma-ray) using balloons and satellites. Currently a 2–20 keV x-ray telescope onboard an Indian satellite is operational. The institute operates a fully fledged balloon facility in Hyderabad that can launch 500–1000 kg payloads to altitudes of 42–35 km.

Taurids

A meteor shower that takes place in October and November. There are two radiants in the constellation Taurus, at dec. +14° and +22°. The meteor stream consists of debris ejected from the now feebly active Comet 2P/Encke over a period of several thousand years, and is one of the most evolved streams encountered by the Earth. The stream has spread out over a broad swathe of the inner solar system, and Taurid shower activity lasts for six weeks, with low but steady rates of slow, bright meteors. The Earth also passes through the stream between 5 June and 18 July, producing the daytime *Beta Taurid* shower. Although they are not observable visually, as the radiant is near the Sun, radio observations indicate that the Beta Taurids are highly active.

Taurus

(the Bull; abbrev. Tau, gen. Tauri; area 797 sq. deg.) A northern zodiacal constellation which lies between Aries and Orion, and culminates at midnight in late November. It is one of the oldest constellations, dating back to when the Sun was in that part of the sky at the vernal (spring) equinox, between about 4000 and 1800 BC. Later, in Greek mythology, it was identified with the form assumed by Zeus when he carried away Europa, daughter of King Agenor of Phoenicia. On early celestial charts only its head and forequarters are shown. Its brightest stars were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A conspicuous constellation, Taurus is easily recognized by virtue of α Tauri (Aldebaran), a red giant (K5) irregular variable (range 0.75–0.95), which marks the bull's right eye and is the top-left star of a V-shaped grouping of a couple of dozen more distant naked-eye stars, which mark the bull's face and represent the brightest members of a scattered open cluster of several hundred stars, the Hyades.

Other bright stars include β Tauri (Elnath, formerly designated γ Aurigae), magnitude 1.7, η Tauri (Alcyone), magnitude 2.9 and the brightest member of another open cluster, the Pleiades, θ^2 Tauri, magnitude 3.4, the brightest member of the Hyades and the brighter component of a wide, naked-eye double with θ^1, magnitude 3.8, separation >5′, which has the same proper motion, and λ Tauri, an Algol-type eclipsing binary (range 3.4–3.9, period 3.95 days). There are ten other stars brighter than magnitude 4.0. Other interesting stars include the variables T Tauri (range 9.3–13.5), the prototype of a class of young stars that exhibit irregular variability, which is located in Hind's Variable Nebula (NGC 1555), a small reflection nebula which shows major variations in brightness and extent, and RV Tauri (range 9.8–13.3, period about 79 days, superimposed on a longer cycle of about 1224 days), the prototype of a class of highly luminous pulsating variables.

The Pleiades (M45), one of the most beautiful objects in the sky, is popularly called the 'Seven Sisters', as about that number of stars can readily be seen with the unaided eye, though there are about 100 stars in the cluster as a whole, embedded in a faint reflection nebula, the brightest part of which (NGC 1435) extends for about 20′ south of 23 Tauri (Merope), magnitude 4.1. Other interesting objects in Taurus include the Crab Nebula (M1, NGC 1952), the brightest (eighth magnitude) supernova remnant in the sky, at the center of which is the Crab pulsar, which marks the spot where a supernova was observed in 1054. It is a source of strong emission at both radio and x-ray wavelengths (where it is known as Taurus A and Taurus X-1, respectively).

The Taurid meteor shower appears to radiate from the constellation (as does the Beta Taurid shower, which cannot be observed visually as it occurs during June and July, when Taurus is close to the Sun).

Taylor, Joseph H (1941–)

Radioastronomer, born in Philadelphia, PA, Nobel prizewinner for physics in 1993 with RUSSELL HULSE 'for the discovery of a new type of pulsar, a discovery that has opened up new possibilities for the study of gravitation'. Interested in radio as a boy, he became a professor at the University of Massachusetts, Amherst, and with his research student Hulse searched with the Arecibo radio telescope for pulsars. They discovered the *Hulse–Taylor pulsar*, PSR 1913 + 16, a binary pulsar that showed general relativistic effects, including loss of energy by gravitational radiation. Taylor helped found the Five College Radio Observatory, where the observations of the Hulse–Taylor pulsar were actually carried out, confirming EINSTEIN's theory of general relativity.

Tectonics

The theory of tectonism—an umbrella term for processes that shape the surface features of a planetary body through forces generated in its crust by heating or cooling in its interior. Tectonic forces can be generated in bodies that have undergone differentiation and have developed a molten mantle beneath the crust. Global heating will cause the entire crust to expand, creating tensional forces in the crust; global cooling will cause it to contract, creating compressive forces. Lunar rilles are examples of features caused by extension of the crust as it expanded. On Mercury, extensive lobate scarps—long, cliff-like features—have been interpreted as resulting from compressive stress caused by global contraction. Wrinkle ridges, found on most of the terrestrial planets, are also compressive features. Localized heating in the mantle producing upwelling of material can cause local uplift of the crust above, as has occurred on Venus to create the mountainous region Maxwell Montes. The Earth's crust consists of segments known as *plates* which move slowly with respect to one another, driven by convection currents in the mantle; *plate tectonics*, as this process is known, was thought to be unique to the Earth, but it may also have operated on Venus. Tectonic processes have also shaped the surfaces of Europa and Ganymede, and of some of the satellites of Saturn and Uranus, including Enceladus and Ariel.

Tektite

A small rounded piece of natural glass, green, black or brown and typically centimeter-sized. Once believed to have a volcanic origin or to be peculiar meteorites, they are now thought to have been formed by the impact of kilometer-sized asteroids. Their composition, mainly silica with some metal oxide content, is consistent with the rapid melting of terrestrial rock under a large impact and the subsequent rapid cooling, from a temperature of 1500–2000 K, of molten droplets splattered into the atmosphere. Their various shapes support this view: many are disk-shaped or show flanges, suggesting surface reheating during their flight. The ages and geographical distribution also support the impact origin theory. They are found in four main locations, known as *strewnfields* (see table 1). The tektites found in a strewnfield have nothing in common geologically with their surroundings, and in three out of the four cases there is an identifiable impact structure. The absence of a confirmed impact crater for the Australasian strewnfield is problematic. There are also *microtektites*, microscopic glass spherules associated for example with the Chicxulub basin, and other types of impact glass found close to other craters.

Table 1. Tektites: the four strewnfields.

Strewnfield	Age (Myr)	Impact structure (approximate diameter)	Approximate number of tektites recovered
Australasian	0.8	?	700 000
North American	35	Chesapeake Bay, US (90 km)	2000
Ivory Coast	1	Bosumtwi Crater, Ghana (10.5 km)	2000
Central European	15	Reiskessel, Germany (24 km)	55 000

Telescope

An instrument that is used to study distant objects. An optical telescope uses a convex lens (the objective, or object glass) or a concave mirror (the primary mirror), or in some cases a combination of both, to collect light from, and form an image of, a distant object. The image produced by the collector may be recorded photographically or electronically. When used for direct visual observation, a telescope also incorporates an eyepiece, a short-focus lens that enables the eye to view a magnified (enlarged) version of the image produced by the collector. An eyepiece may also be used to project an enlarged image onto a photographic emulsion or electronic detector.

If the collector is a lens, the telescope is called a refractor, whereas if the collector is a mirror, the telescope is a reflector. A catadioptric telescope uses a combination of lens(es) and mirror(s) to collect light and form an image.

A telescope is categorized by its aperture (the clear diameter of the collector) and focal length or focal ratio, the former being the distance between the collector and the image that it produces, and the latter being the ratio of the focal length to the aperture. Because a telescope collects more light than the unaided human eye, it can reveal fainter (and more distant) objects than the eye alone; the larger the aperture, the greater the light gathering power. The ability of a telescope to reveal fine detail (resolving power) also depends on the aperture. The size of the image produced by a telescope is directly proportional to the focal length of the collector. Additional lenses or mirrors may be used to increase the effective focal length of the telescope and thereby produce larger images.

The objective lens of a refractor usually consists of at least two components, each of which has front and rear surfaces. Consequently there are at least four surfaces that must be figured (ground to a precise shape). By contrast, because light is reflected from the front surface of an astronomical mirror, only one surface needs to be figured. Furthermore, lenses can be supported only around the perimeter, while mirrors can be supported across the back as well as round the edge. For these, and other, reasons, large reflectors are easier and cheaper to construct and, in most respects, are more efficient. All large modern optical telescopes are of the reflecting type, the largest being the two Keck telescopes, each with an aperture of 10 m, that are located on Mauna Kea, Hawaii.

The invention of the telescope is usually credited to the Dutch spectacle-maker, Hans Lippershey (*c*. 1570–1619), who constructed a simple refractor in 1608. However, some historians contend that a form of telescope may have been constructed and used by the Englishman, Leonard Digges, in or around 1550. Although the Scot, James Gregory (1638–75) had produced a design for a reflecting telescope in 1663, the first working reflector is generally believed to have been designed and constructed in 1668 by the English natural philosopher Isaac Newton (1642–1727).

The term 'telescope' is also applied to instruments that collect radiation, and enable images to be produced, at wavelengths ranging from x-rays to radio waves.

Telescope Engineering

The design and construction of modern astronomical telescopes and instruments is one of the most challenging domains of engineering encompassing many fields including in particular optics, structures, mechanics, control systems, thermal and atmospheric physics. In this article we examine the main engineering approaches and practices in use in modern optical telescopes on the ground and in space.

Astronomical observatories as systems

Astronomical observatories are tightly integrated systems where most subsystems are strongly interacting and individual subsystem performances must be traded against one another in order to arrive at an optimum design. Since the image quality of a telescope is one of the most important performance characteristics (others include observing efficiency and spectral coverage), an essential step in this process is to establish an 'optical error budget' where all the contributing factors are evaluated. An example of such an error budget is shown in figure 1. As the design progresses, the individual allocations are re-estimated and traded against each other as need be until a satisfactory set is obtained. Cost and schedule have to be taken into account as well, and observatory performance has itself to be traded against scientific goals until the overall project optimum is determined.

The availability of high-fidelity computer modeling offers an ideal solution to this problem. It is now possible to develop a detailed computer model of the entire system (optics, structure, thermal, control systems etc), simulate operating conditions and explore the trade spaces to find the best configuration according to performance and cost criteria.

Optics

All large telescopes are of the REFLECTOR type because of the difficulty in producing lenses of sufficient purity in size larger than 1 m in diameter. Additional reasons are that lenses are generally heavy since they cannot be 'lightweighted' and they suffer from chromatic aberrations which can be corrected only over a narrow spectral range. Optical configurations are relatively simple and the Ritchey–Chrétien Cassegrain combination is almost universally used. In practice, as many optical surfaces are needed as the number of aberrations one wishes to correct. With two surfaces, the Ritchey–Chrétien configuration is able to correct spherical aberration and coma. Correction of astigmatism requires an additional surface which can be part of the telescope (three-mirror system) or incorporated into each instrument.

The choice of the f-ratio (ratio of final focal length to entrance aperture diameter) is the result of a complex tradeoff between imaging quality requirements, field of view, size of the secondary mirror, size of the instrument entrance optics, focal length of the spectrograph collimators and detector pixel size.

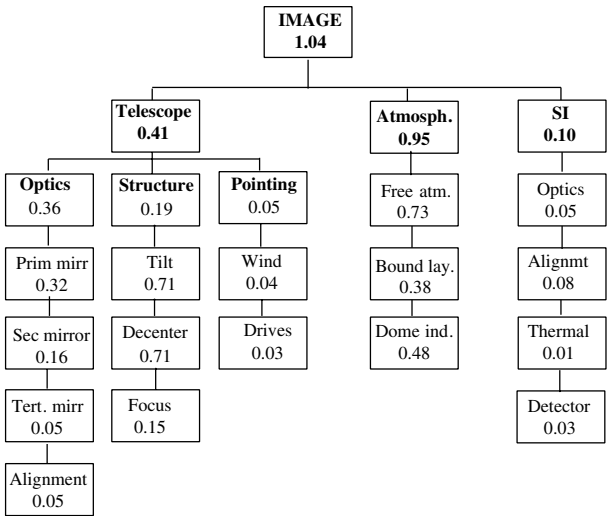

Figure 1. Optical error budget of the Keck 10 m telescope expressed in diameter of the image in arc seconds that encloses 80% of the total image energy.

For the simple case of a space telescope with diffraction-limited optics directly feeding a critically sampled camera (2 pixels per resolution element, i.e. λ/D), the f-ratio needed is given by:

$$\frac{f}{D} = \frac{2p}{\lambda}$$

where λ is the wavelength and p is the pixel size. Current detectors have pixel sizes ranging from 7 to 13 μm for CCDs and 18 to 28 μm for near-infrared detectors which results in f-ratios in the $f/15$ to $f/30$ range, which is well adapted to the Cassegrain combination.

For a ground telescope where atmospheric SEEING limits image quality to about 0.4", adequate sampling for imaging would require much faster f-ratios—in the $f/2$ to $f/4$ range for an 8 m class telescope. This can be obtained directly at a prime focus or with a focal reducer at a Cassegrain focus.

Spectrographs are generally used at the Cassegrain focus and fed with an f-ratio between $f/8$ and $f/15$.

The problem with Cassegrain foci is that the volume of the instruments is limited by mount clearance. Large and heavy instruments are better located at the 'Nasmyth' focus (figure 2). An additional advantage of the Nasmyth focus is that the instruments keep a fixed direction with respect to gravity which greatly simplifies their design.

Very high spectral resolution spectrographs are too bulky to be mounted on the telescope itself (even at the Nasmyth focus), and are best left Earth-stationary; they are fed via a series of flat mirrors at the so-called 'coudé focus'. In such cases a much slower f-ratio is used ($f/30$ to $f/100$) in order to reduce the size of the beam to be transferred.

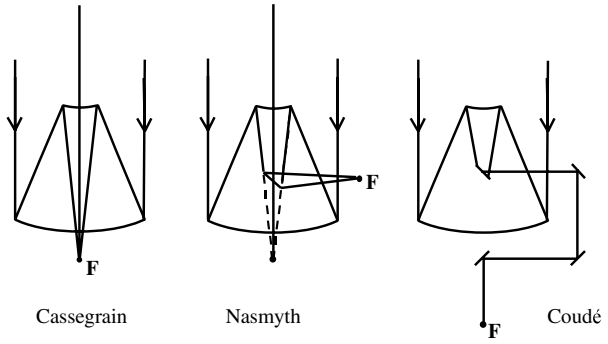

Figure 2. Cassegrain, Nasmyth and coudé focus arrangements

Materials

Contrary to many engineering situations, telescope structures are not driven by stress conditions, but by deflection under load (on the ground) or dynamic effects (on the ground and in space).

The governing equation for the deflection of a mirror (plate) under gravity is of the form:

$$\delta = k\frac{\rho}{E}\frac{D^4}{t^2}$$

where k is a constant the value of which depends on the geometry of the support, D is the diameter, t the thickness, ρ the material density and E is the Young modulus (elasticity modulus) of the material.

Similarly, the deflection under gravity of a beam supporting optical components of negligible mass compared with the mass of the beam (which is roughly the case of the tube supporting the secondary mirror in a Cassegrain telescope) is given by:

$$\delta = k\frac{\rho}{E}l^4$$

where k is function of the beam geometry and support and l is the length of the beam.

In both cases, the material properties enter as the ratio of the Young modulus to density (E/ρ); this ratio is referred to as 'specific stiffness'. The larger this ratio, the smaller the deflection will be. The same ratio also enters the laws governing dynamic effects due to wind or internal disturbances.

For large telescopes, whether on the ground or in space, weight is a dominant issue and the most advantageous materials will be those with high specific stiffness. As shown in table 1, the materials commonly used in making mirrors and telescope structures (glass, aluminum, steel) have about the same E/ρ. It is in particular seen that aluminum does not offer any advantage over steel. Steel is less expensive and is the material of choice for ground-based telescopes structures. Three materials stand out, however: silicon carbide, graphite epoxy and beryllium. For the same stiffness they offer a gain of four to six times in mass over steel and aluminum. They are expensive materials to produce, however, and are limited to space applications where mass is at a premium.

Table 1. Mechanical and thermal properties of major mirror and structural materials used in optical systems. ρ is the density, E is the Young's modulus, α the coefficient of thermal expansion, λ the thermal conductivity and C_p is the specific heat.

Material	ρ (kg m^{-3})	E/ρ (10^6 s)	α at 300 K (10^{-6} K^{-1})	$\lambda/\rho c_t$ (10^{-6} m^2 s^{-1})
Pyrex	2500	25	3.3	0.60
Fused silica	2200	33	0.5	0.86
ULE	2200	31	0.03	0.77
Zerodur	2500	36	0.10	0.77
SiC	2600	96	3.5	86
Beryllium	1800	162	12	5.4
Aluminum	2700	26	25	4.0
Steel	7800	27	12	5.7
Graphite epoxy	1740	61	0.09	29

Mirrors must also retain their correct surface shape in spite of environmental temperature changes which can be up to several degrees celsius. Changes in bulk temperature induce focus variations and gradients within the mirror will induce distortion of the optical surface. For these two effects to be negligible the mirror material should have a coefficient of thermal expansion of 10^{-6} or lower. Pyrex, first used on the 5 m Hale telescope, was a major improvement over regular glass, but the problem really only disappeared with the use of fused silica (HST mirror) and the development of ceramic glass (Cer-Vit, Zerodur) and ULE (ultra-low-expansion fused silica) which have coefficients of thermal expansion in the 10^{-6}–10^{-8} range and are used in most large ground-based telescopes today.

Although the mirror may retain its shape in a changing thermal environment due to a low coefficient of thermal expansion, the temperature difference between the mirror and the ambient air can generate convective turbulence ('mirror seeing') detrimental to image quality (see section on local seeing control below). This effect will be the smallest for materials which have a high thermal diffusivity ($\lambda/C_t\rho$) where λ is the conduction and C_t is the specific heat of the material, so that they track the ambient temperature variations well. None of the glass/ceramic materials are very good from that point of view and mirror seeing has to be mitigated by minimizing mass and by ventilation (see 'controlling man-made seeing' below).

In space, where mirror seeing is not a concern, high diffusivity can still be useful when the observatory is subjected to bulk temperature variation as when repointing but, in general, it will be more advantageous to avoid the thermal effects entirely by having as low a coefficient of expansion as possible. The best mirror blank materials for space application are thus those which have a high intrinsic stiffness and a low-expansion coefficient at operating temperature. For ambient temperature operation, low-expansion glass-type materials (ULE,

Dirac House, Temple Back, Bristol, BS1 6BE, UK

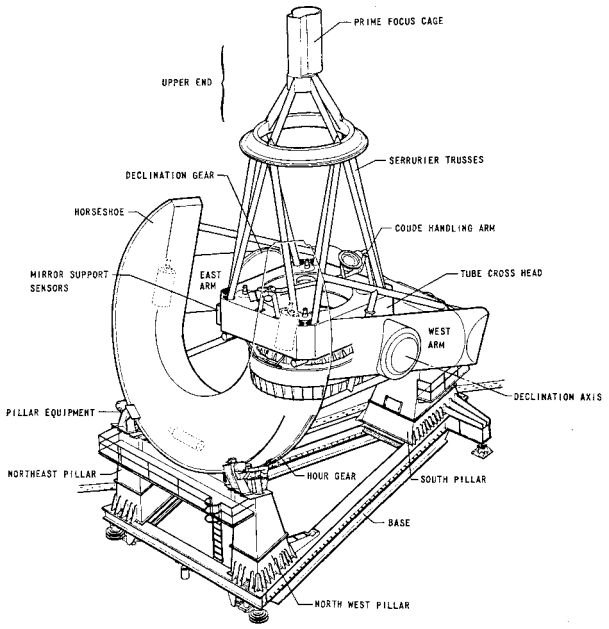

Figure 3. Main components of a telescope.

Zerodur) are best in spite of their lower intrinsic stiffness. For cryogenic operation (40 K), however, the best materials are beryllium and SiC because of their low coefficient of thermal expansion at cryogenic temperature (in the 10^{-7} K^{-1}) and high specific stiffness.

Finally, mirror materials must be able to be polished to a high degree of smoothness and be dimensionally stable. Amorphous materials like glass and ceramics produce very smooth surfaces while metals usually end up with a much coarser surface finish suitable only for infrared application (50 Å rms) unless they are coated with nickel prior to polishing.

Mechanical design

The main components of a ground-based telescope are shown in figure 3.

Because of the extraordinary precision to which the optical components must be fabricated (fraction of a wavelength or 1/10 to 1/100 of a micron), kept aligned (1 to 10 microns), and pointed (1/10 to 1/100 of an arc second), deflection under gravity, mechanical disturbances and temperature variations must be avoided or compensated for. In what follows we give an overview of the techniques which have been developed over the years to reach this goal.

Kinematic mount

To avoid deforming the very high-precision figure of the optical components, it is essential that strains in their supporting structure not be transmitted to the optics. The usual method consists of using a *kinematic mount*. A rigid body in space has six degrees of freedom: translation along and rotation about each of three orthogonal axes.

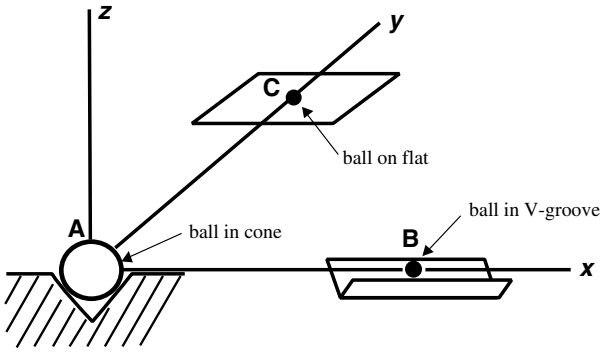

Figure 4. Principle of the kinematic mount. Alternate implementations, all following the same principle, are diverse.

The body is fully constrained when each of these possible movements is individually prevented. If one movement is constrained in more than one way, then the body will strain when its support structure deforms. A kinematic mount is a mounting system which does not constrain more than these six degrees of freedom. The simplest example is that of the traditional 'point/V-groove/plane' support (figure 4). Kinematic mounts are ubiquitous in telescopes. They are used not only to mount mirrors in their cell, but also to mount the instruments on the telescope tube and to support telescope mounts on their pier (see also TELESCOPE MOUNTINGS).

Mirror mounts

Up to about 30 cm in diameter, a ground-based telescope mirror can be made stiff enough to be considered a rigid body and mounted kinematically. Larger mirrors would bend beyond tolerable limits and it is necessary to have additional supports to compensate for gravity but without interfering with the stress-free condition afforded by the kinematic mount. This is done by 'floating' the mirror in a set of discrete forces or in pressure/vacuum so as to balance its weight (figure 5). This is accomplished by counterweight lever systems, regulated air pressure or force actuators with feedback control.

Space telescopes do not suffer from gravity deflection, but since gravity release is difficult to measure on the ground, force actuators are sometimes placed on the back of the mirror to make minute corrections to its figure once on orbit.

Telescope tube

In a ground telescope the primary and secondary mirrors of a Cassegrain system must remain parallel to each other and aligned in spite of the changing effect of gravity as the tube rotates to follow a target. The cylindrical telescope tube which is commonly used on small telescopes does not satisfy this condition as the two ends are tilted with respect to each other (figure 6). The solution to this problem is to use a truss consisting of members arranged in isosceles triangles on a square base. This forces the

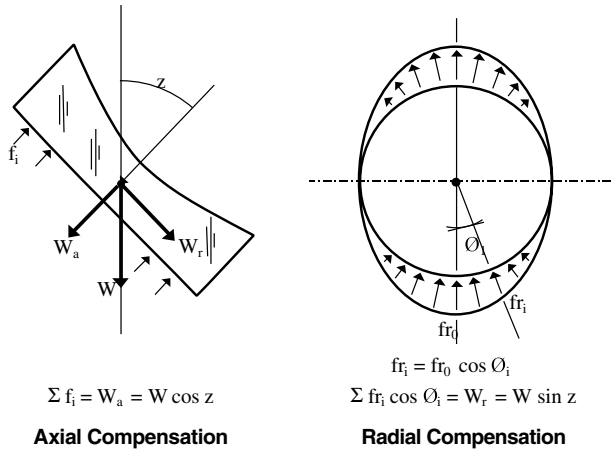

Figure 5. Forces are applied to the back and edge of the mirror to compensate for gravity and minimize deflection.

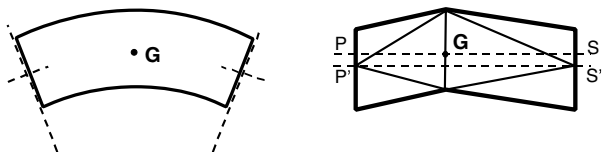

Figure 6. After deflection under gravity the two ends of a cylindrical tube do not remain parallel. In the 'Serrurier truss', the two ends, say the primary and secondary mirrors, stay parallel to each other and deflect by the same amount, maintaining collimation.

two ends (supporting the primary and secondary mirrors) to undergo parallel translations, and with proper sizing of the member sections the two translations can be made equal. This design, called the 'Serrurier truss' after Max Serrurier who invented it for the 5 m Hale telescope at Mount Palomar, has been used in most large telescopes ever since.

Balancing systems

Ground-based telescopes need to be extremely well balanced around their axis of rotation in order to minimize driving torques and differential flexure. This is done by adding or removing fixed weights or using motor-driven balancing weights. The procedure has to be done at each optical configuration change (e.g. exchange of the telescope top unit when changing from Cassegrain to coudé) and each time a focal instrument is replaced or installed.

Hydrostatic bearings

Although the tube and the mount of a ground-based telescope are extremely well balanced, the torques necessary to rotate the heavy tube and mount of a large telescope (of the order of 100 tonnes for the tube and up to 300 tonnes for the mount) must be small enough to avoid torsional deformation and potential optical misalignment. Large driving torques would also create heat dissipation

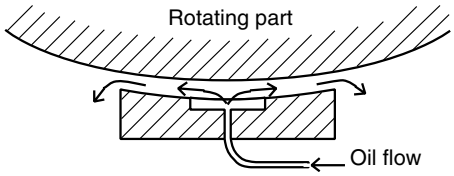

Figure 7. Principle of the hydrostatic bearing used to support the rotating parts of a telescope (tube and mount) with minimal friction.

in the dome, which is detrimental to image quality. During observations, the telescope tracking must also be extremely smooth. Mechanical bearings such as roller bearings suffer from 'stick-slip' at very low speed, a phenomenon due to stress build-up and relaxation at the contact areas, resulting in a jittery motion which is generally beyond the correctability of automatic guiding systems. These problems are solved by the use of hydrostatic bearings (figure 7) first developed for the 5 m Hale telescope and which are now almost a universal choice in modern large telescopes. The tube and mount journals are supported on pads which are accurately machined to match, and oil is pumped in between at high pressure in order to raise them and leave them floating on a thin film of oil (of the order of 0.1 mm thick). With hydrostatic bearings, the rotation torques are so low that they are negligible compared with the resisting torques due to the cable wrap-ups or slip rings used to transfer energy and data to the moving parts.

Active optics

For telescopes much larger than 4 m, the traditional measures taken to keep the figure of the mirrors undisturbed and the optical train aligned become increasingly difficult to implement. Instead of relying on passive means to compensate for gravity and thermal effects, it becomes advantageous to use an active system where the optical quality is monitored in permanence using a reference star, and the figure and respective positions of the main optics elements are adjusted accordingly. This approach is referred to as 'ACTIVE OPTICS'. All telescopes of the 8–10 m class use some form of active optics (figure 8). Because gravity and thermal effects vary slowly, the bandwidth of active optics is typically of the order of 1 Hz or less. This is to by opposition to 'adaptive optics' which is used for correction of atmospheric seeing which has a bandwidth up to 1000 Hz.

Pointing and tracking system

Early telescopes were all of the equatorial type which once pointed at the desired target only requires rotation at a constant rate (15" s^{-1}) around the polar axis to track the target. This hour angle motion was accomplished in an 'open loop' fashion by a clock mechanism and more recently by a synchronous motor. With the need for better accuracy and regulation, all modern telescopes use 'feedback control', where the actual motion of the

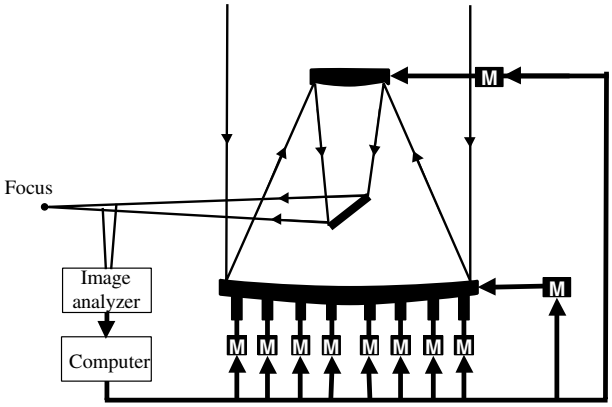

Figure 8. Primary mirror cell of the ESO Very Large Telescope. The 8 m mirror is supported on actuators which are adjusted continuously to compensate for gravity and thermal effects.

rotating axis is constantly compared with the desired value and the error fed back to the drive system to correct it. Feedback control is intrinsically more accurate and eliminates the need for high-precision gearing and drive systems. It also allows for the correction of atmospheric refraction, deformations of the telescope structure under gravity and of disturbances as long as they are within the bandwidth of the control system. With the assistance of computers, feedback control is also well adapted to producing the variable tracking speed needed for the ALTAZIMUTH MOUNTING (alt-az mount).

The limitation to the accuracy of pointing systems is due to disturbances beyond the bandwidth of the pointing system, which is generally a few Hertz at most. On the ground the main source is wind shake. With the need to largely open the dome during observations in order to reduce self-induced seeing (see section on man-made seeing below) the telescope is left largely unprotected from wind action, which results in wind buffeting on the primary mirror and on the tube supporting the secondary mirror. This effect can be lessened by reducing the cross section of the telescope structure members, by stiffening the secondary mirror support system and by actively controlling the primary mirror. In INFRARED TELESCOPES, chopping secondary mirrors used for background subtraction are another source of disturbance. This can be reduced to a large extent by compensation, that is to say by moving a dummy mass behind the mirror in the opposite direction so as to eliminate the chopping disturbing torque.

In space, the main source of uncorrected disturbance comes from the vibrations induced by thermal snaps or by moving parts such as reaction wheels, antennas, fuel slosh and tape recorders.

The absolute pointing accuracy of telescopes is typically about 1 arc second rms. Blind offsets from calibration stars are accurate to better than 0.1 and 0.01 arc second for ground and space telescopes respectively. Tracking stability of ground telescopes is typically better than 0.1 arc second without recourse to any guide star over periods of several minutes. By closing the loop on a guide star (see 'Guiding' below), the line of sight jitter is typically under 20 milliarc seconds rms for ground telescopes and a few milliarc seconds for the HUBBLE SPACE TELESCOPE.

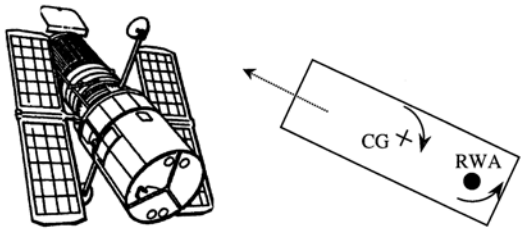

Figure 9. Reaction wheels are used to point a space telescope.

Drives

Until the 1970s ground telescopes generally used a worm gear system because of its high gear ratio and excellent intrinsic accuracy which permitted open loop tracking using a constant speed motor. Worm gears are expensive and limited in size, however, and large modern telescopes use spur gears, friction drives or even direct drives, all with feedback control from an attitude sensor. Spur gears offer more positive control (no risk of slippage), but friction roller drives are cheaper and inherently smoother. The ultimate choice is a direct drive which eliminates all mechanical systems. This is being used in the European Southern Observatory Very Large Telescope (VLT) where the rotor and stator of each axis motor are integrated in the structure.

Space telescopes cannot be driven by reacting against the ground; they use momentum transfer instead. The Hubble Space Telescope uses a set of flywheels, one for each axis plus a spare, rotating up to 3600 rpm, called 'reaction wheels'. To slew the telescope to a new target, the reaction wheels' spin speed is increased or decreased depending on the desired direction. Because the overall momentum remains constant, the telescope moves in the opposite direction (figure 9). To stop it when it approaches its target, the reaction wheel speeds are returned to their original values.

Sensors

On ground-based telescopes the position of each axis is measured by encoders which are now almost always of the optical type. Incremental encoders with a high angular resolution (e.g. 0.1 arc second), but no absolute accuracy are used for tracking. They are generally mounted on a gear or friction system for increased magnification. Absolute encoders, generally mounted directly on a large journal are used for absolute pointing determination and have an absolute accuracy of about 1 arc second.

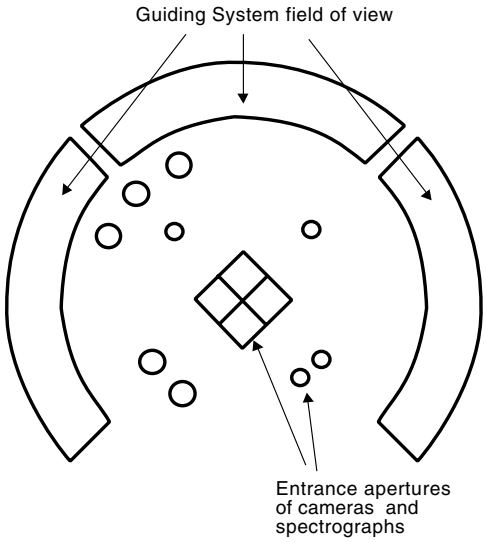

Figure 10. Focal plane of the Hubble Space Telescope showing the three zones used for guiding.

For space telescopes, the main attitude sensors are generally gyroscopes, the drift of which are corrected by star trackers. The star trackers have a field of several degrees and the best ones have an absolute accuracy of about 2 arc second rms.

Guiding

By itself, telescope tracking is not accurate enough for more than a few minutes at best. On the ground, the limit comes from errors in the gravity compensation systems, encoder imperfections, atmospheric refraction and atmospheric turbulence. In space, the limit is due to the spacecraft star-trackers sensing noise and from gyroscope drift. It is necessary to adjust the line of sight finely by monitoring the position of a relatively bright star in the vicinity of the field being observed. This is referred to as 'guiding'. Early telescopes used GUIDE TELESCOPES mounted on the side of the telescope tube. But it is very difficult to ensure that the line of sight of the guide telescope remains parallel to that of the main telescope whatever its inclination. It is much better to guide using a star in the very field of the telescope (figure 10). This eliminates line of sight differential errors and the guiding system benefits from the full aperture of the main telescope, thus improving its sensitivity.

The error signal supplied by the guider can be fed directly into the pointing system, but the bandwidth of the correction can be improved by 'fine steering' the optical beam itself instead of the entire telescope. This is accomplished by the tip/tilt of a mirror in the optical train such as the secondary mirror, or, better, by using a dedicated, low-inertia, flat mirror located at a real pupil just before the focal plane.

Dome and building

Ground-based optical telescopes are too complex and too precise to be left without protection against sunlight, heat, and adverse weather. Some kind of enclosure is necessary. In addition, OBSERVATORIES require a certain amount of supporting equipment and storage space for scientific instruments, all of which need to be located in the immediate vicinity of the telescope. These must also be protected from the elements. Contrary to RADIOTELESCOPES, optical telescopes are thus always installed inside an enclosure which is closed during the day and opened during observations.

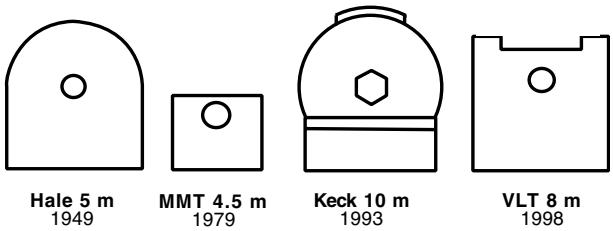

Figure 11. Evolution of dome and building size compared with telescope diameter.

The telescope enclosure can amount to 20 to 40% of the total cost of the observatory, however, and the recent trend has been to keep costs down by using primary mirrors with fast f-ratios and by switching from EQUATORIAL MOUNTINGS to alt-az mounts. Figure 11 shows how dramatic the reduction of enclosure size has been over the last 50 years.

While the enclosure protects the telescope and telescope chamber from heating by the Sun during the day, it can be a source of image degradation at night because any temperature difference between the enclosure and the ambient air will generate convection cells which may travel into the line of sight. The problem is due only to the mixing of air parcels at different temperatures from the ambient, not to pressure fluctuations due to aerodynamic effects, as the corresponding change in the refraction index of air is negligible.

In the best astronomical sites, the temperature drop at night is small (annual mean of 1.3 °C from sunset to sunrise at Mauna Kea, Hawaii), but there are frequent short-time-scale fluctuations that a large thermal capacity system simply cannot track (standard deviation of 0.5 °C and average time derivative of 0.6 °C h^{-1} in the case of Mauna Kea). A very short thermal time constant is essential. To minimize these effects the current philosophy, first implemented in the 1980s on the pathsetting MMT Telescope, is as follows:

- the telescope structure and optics should be designed for a very low thermal inertia (lightweighted or thin mirrors, 'open' structures);
- the dome should be wide open at night to maximize exposure of the telescope to ambient air and thus quickly reach thermal equilibrium.

A fully opened dome results in an airflow which is generally fully turbulent with a Reynolds number of $\sim 10^6$–10^7, but turbulence *per se* is not a source of degradation if the flow is isothermal.

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

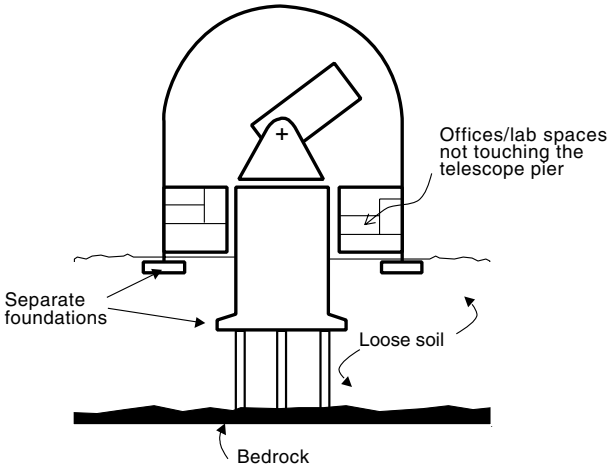

Figure 12. Separating the foundation of the building from that of the pier to minimize transmission of dome windshake.

In this new approach it is important, however, that the entire enclosure be well flushed. If there are pockets of air at different temperatures, then turbulence can mix these different regions and contribute to image degradation. The more open the enclosure the better, with open-air operation being the ultimate. The drawback is that in windy conditions, telescope shake will begin to become dominant, so that a compromise between thermal effects and dynamic effects has to be found.

The building and dome present a very large projected area normal to the direction of the wind. The associated overturning moment causes additional forces on the building foundations which can be expected to propagate through the soil and into the pier supporting the telescope. The effects are strongly dependent on the type of soil, on whether it is rock or particulate. In general transmission is reduced if (figure 12):

- the building foundation is structurally separate from the pier foundation;
- connections between the building and the pier and telescopes (cabling) are minimized and elastic;
- the building foundations are built over a damping layer (sand, lava cinder), while the pier is mounted on bedrock;
- the pier foundation is at a lower level than the building foundation.

Control of man-made seeing

Temperature inequalities between the ambient air and the mirrors, telescope structure and enclosure create convective turbulence along the path near the telescope which can easily degrade image quality as much as poor optics or a misaligned system. Designers of large telescopes since the 1960s have taken great care to reduce this effect in order to benefit fully from the intrinsic quality of the observatory sites. As explained above, enclosures are designed to have low thermal time constants and ventilation gates so that they can be flushed effectively either by wind or active ventilation so as to reduce 'dome seeing'. But there are several other possible sources of 'man-made seeing' which should be minimized or avoided.

Convective turbulence above the primary mirror can develop for temperature differences as little as a fraction of a degree, especially when the mirror is at a temperature higher than ambient (a 1 °C temperature difference will introduce up to 0.5 arc second of image degradation). This is a difficult problem to solve because of the enormous mass of the mirror which has a time constant of several hours. This 'mirror seeing' can be reduced by several measures: (a) minimizing the thermal time constant of the mirror so that it can follow changes in ambient temperature relatively rapidly, (b) cooling the dome during the day to a temperature close to that of the following night, (c) choosing sites where the temperature drop during the night is minimal. The thermal time constant can be reduced by decreasing the thermal mass of the mirror or by increasing the convective heat transfer between the mirror and the atmosphere. For example, a ribbed honeycomb structure can be incorporated in the back side of a mirror to both make it lighter and increase its surface area. Forced convection (fans) can be added to further reduce the thermal time constant.

It is also important to minimize the heat generated in the telescope chamber coming from electronic racks and oil circulating in the hydrostatic pads, as well as from people. This can be done by cooling, active ventilation, exhausting the warm air away from the building, and by placing the control rooms away from the telescope chamber.

Costs

Large astronomical telescopes represent major investments which require careful estimating and cost control during the design and construction phases. Until the early 1980s, the cost of equatorial telescopes followed a well established cost function of the aperture diameter to the 2.7th power (figure 13). Using the same technology, building 8–10 m class telescopes would have been unaffordable. But fortunately a series of technological improvements made it possible: mastering of the aspheric polishing process permitted the use of faster primaries (hence shorter telescopes), better testing methods and computer polishing took the optical figuring process from a black art to a deterministic science, the use of the stressed mirror or stressed-lap techniques reduced the polishing time drastically, the use of the alt-az mount instead of the equatorial mount reduced overall mass and thus cost, and the advent of computer control made active optics possible and allowed for more efficient pointing systems. This lowered the cost of telescopes by an order of magnitude, although the diameter relationship is still around the same power law. To enable the extremely large telescopes (25 to 100 m in diameter) which are now under consideration, similar

technological innovations will be needed, perhaps by using spherical or fixed primary mirrors.

Telescope Mountings (for Amateur Astronomers)

Mounting a telescope is of paramount importance. Unless the instrument is absolutely steady, it will be quite useless, particularly as the field is bound to be comparatively small—and, of course, the higher the magnification, the more restricted the field.

The simplest form of mounting is the altazimuth. The telescope can move freely in any direction, either up and down in altitude, or east and west in *azimuth*. Some small telescopes are sold on what are termed pillar-and-claw mounts, which look very nice, but are about as steady as blancmanges. A proper tripod is much better, and if need be a camera tripod can be adapted, although it must be very firm (see ALTAZIMUTH MOUNTING).

There is an ever-present problem. As the Earth spins on its axis from west to east, the entire sky seems to rotate from east to west, so that a telescope has to be continuously shifted so as to keep the target object in view. With an altazimuth there are two separate motions to be taken into account, and hand-guiding can be awkward. Slow motions can be added, and this certainly helps, but it is fair to say that using an altazimuth telescope for photography, when a time exposure is needed, is very difficult—although with sufficient skill and patience it can be done.

Most telescopes of more than 3–4 in aperture—either REFRACTORS or REFLECTORS—are given EQUATORIAL MOUNTINGS. One common type is the German. Here there is a polar axis which is aimed at the pole of the sky, so that it is parallel to the axis of the Earth; the telescope is mounted on one end of the polar axis, and there is a counterweight on the other end. When the telescope is moved round in azimuth (right ascension) the up-or-down movement will look after itself. Manual slow motions can be fitted, but the ideal is to add a driving mechanism, usually electrical, so that the telescope is moved round at a rate which exactly compensates for the rotation of the Earth. Once the target object has been put into the field of view, it will stay there—provided that the polar axis is correctly aligned and that the driving clock is running at the correct rate. For most types of serious observational work a driving clock is more or less essential. Many older telescopes, usually refractors, were driven by a mechanism involving falling weights, and this does at least have the advantage of being unaffected by any changes in the supply of electricity.

There are many forms of equatorial mounts. With the Fork, the polar axis is mounted between pillars and the telescope is pivoted inside it. The English pattern has the polar axis fixed at both ends, and this makes for real stability, but there is the disadvantage that the telescope cannot be pointed near the celestial pole, so that there is a part of the sky which is inaccessible; the Mount Wilson 100 in reflector is mounted in this way.

With an equatorial mounting, setting circles can be added so that the telescope can be pointed to any particular object—provided that the right ascension and declination of the object are known, together with the sidereal time. By now there are many computer—controlled small telescopes which can be programmed to swing from one target to another. These are of particular use to observers who are searching for supernovae in external galaxies.

A coelostat is a form of optical instrument which makes use of two mirrors, one fixed and one movable (see SOLARS FEEDS). The light is collected initially by the movable mirror, and this rotates so that the light is reflected in a fixed direction onto the second mirror. This means that the eyepiece does not have to move at all, and heavy equipment can be set up in the position where an eyepiece would have been in former times, when visual observation was always used. The Coudé and Nasmyth optical systems make use of this principle.

The first good, large reflectors were made by William Herschel in the late 18th century; all these were on altazimuth mountings and were awkward to use. Equatorials were then developed, and before long were in common use, but mention should be made of the most remarkable mounting of all—that built by the third Earl of Rosse for his 72 in reflector, completed in 1845. The huge tube was mounted between two massive stone walls and was pivoted at the bottom, so that it could do no more than swing from side to side around the meridian—and it could cover only a relatively narrow strip of the sky; the observer had to wait until the Earth's rotation brought the target object into view. Nothing like the Rosse telescope has been built before or since, but within its limitation it worked well. It has now (2000) been restored and is once more operational, although it is of course of historical value only.

There is, however, one modern development which is of great importance. For many years all large telescopes were equatorially mounted, because otherwise they could not be mechanically driven. This is no longer the case. Computers are now so accurate that a telescope on an altazimuth mounting can be driven just as precisely as if it were on an equatorial, and the altazimuth pattern has many practical advantages. The first large telescope to be set up on an altazimuth was the Russian 236 in reflector at Mount Pastukhov in Russia, completed in 1975. To be honest, the telescope itself has never been a real success; the optics are below standard, and the observing site is mediocre, but the altazimuth mounting set the pattern for all large telescopes which followed, and equatorials have been more or less abandoned for all new professional instruments.

So far as amateurs are concerned, an altazimuth mounting is suitable only when no photography is to be undertaken, and the emphasis is on 'deep sky' observation rather than higher-magnification views of the Moon and planets. Actually, the most elementary form of all is the Dobsonian, in which the telescope is pivoted just above the mirror inside what is to all intents and purposes a box—the box itself being on a rotatable base. Large Dobsonians are becoming surprisingly common, even up to apertures of as much as 24 in, although the fact that they cannot

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

easily be mechanically guided means that they are limited in scope (see DOBSONIAN TELESCOPE).

Making an equatorial mounting is by no means difficult, and an electrical drive can be added if needed. There is no doubt that observing becomes much more pleasurable when the telescope will keep the object firmly in view without having to be constantly adjusted by hand.

One final point is worth making; it is a principle laid down many years ago by W H Steavenson, a well-known amateur astronomer who because a world expert on telescope construction and even served as President of the Royal Astronomical Society. 'If you mean to construct a mount for a telescope', he wrote, 'work out the maximum possible weight that the mounting must be. Once you have decided this—multiply by three.'

Telescopes in History

The precise origins of the optical telescope are hidden in the depths of time. In the thirteenth century Roger Bacon claimed to have devised a combination of lenses which enabled him to see distant objects as if they were near. Others who have an unsubstantiated claim to have invented the telescope in the sixteenth century include an Englishman, Leonard DIGGES, and an Italian, Giovanni Batista Porta, whose spyglass was manufactured in Holland for military purposes.

However, a Dutch spectacle-maker from Middleburg, Hans LIPPERHEY, is usually credited with making the first true refracting telescope in 1608. The new instrument was soon being used by the English mathematician Thomas HARRIOT and by Simon MARIUS in Germany to study the night sky. But it was GALILEO GALILEI, then Professor of Mathematics at the University of Padua in Italy, who was the first to construct a telescope for systematic astronomical observations.

The news of the Flemish invention reached Galileo early in 1609. After a few trials, 'sparing neither labor nor expense', he succeeded in arranging two lenses, one convex and one concave, inside a tube, so that they would magnify an object by a factor of three. This rapidly evolved into a more powerful instrument capable of magnifying objects 30 times (see GALILEAN TELESCOPE).

With his improved telescope, Galileo was able to turn his attention to the heavens. His startling discoveries were described in the book, *Sidereus Nuncius* (*The Sidereal Messenger*), which was published in March 1610. In it he wrote:

> (I have seen) stars in myriads, which have never been seen before, and which surpass the old, previously known, stars in number more than ten times. But that which will excite the greatest astonishment by far ... is this, namely, that I have discovered four planets, neither known nor observed by any one of the astronomers before my time.

This momentous discovery of Jupiter's four major satellites (now dubbed the 'Galilean satellites'; see JUPITER: SATELLITES) demonstrated that bodies other than the Earth might have other objects in orbit around them, and so supported the Copernican view of the solar system.

His telescope also enabled Galileo to produce the first maps of the Moon, revealing its rough terrain along the terminator as it passed through different phases (see MOON MAPS). Venus, too, was shown to have phases. Even the Sun was shown to be blemished as spots appeared and moved across its face (see SUNSPOTS). Evidence from his drawings suggests that Galileo even saw NEPTUNE in 1613, when it was close to Jupiter, but he failed to observe it for long enough to recognize that it was not a 'fixed' star.

Galileo's arrangement of lenses was soon superseded by Johannes KEPLER's system of two convex lenses, though Kepler himself does not seem to have actually built such an instrument. This seems to have been left to an enemy of Galileo, the German Jesuit observer, Christopher SCHEINER (1575–1650), who used his improved version to discover faculae on the Sun.

As the power of refracting telescopes increased, a series of fundamental discoveries were made. For example, by learning to grind lenses with exceptional accuracy and developing an improved eyepiece, Christiaan HUYGENS (1629–95) was able to construct instruments which enabled him to discover Saturn's ring system and its large moon, Titan.

However, refractors had two main disadvantages. The tendency for the object glass (the main lens) to focus different wavelengths of light at different distances caused them to produce rings of false color around stars and planets (CHROMATIC ABERRATION). This effect could be reduced by building telescopes of extremely long focal length, but this, in turn, made them cumbersome and unwieldy.

The largest classical refractor, which was used by Johannes HEVELIUS (1611–87), was 47 m (155 ft) long, and had to be set in place with a hoist. Giovanni Domenico CASSINI (1625–1712) later used a huge refracting telescope at the newly built Paris Observatory—described by Molière as 'an eye-glass to frighten people out of their wits'—to discover the gap in the rings which is named after him. His tubeless instrument comprised a lens which was placed on the balcony of the observatory and pointed more or less in the intended direction, while the observer stood 27 m (89 ft) below in the courtyard, trying to direct the image through a magnifying glass.

In 1671, the same year that G D Cassini moved to the Paris Observatory, Isaac NEWTON presented a revolutionary new telescope to the Royal Society in London. Believing that it would never be possible to make achromatic lenses for refracting telescopes, he designed and built the first practical reflecting telescope. Although its dimensions were modest—the metal mirror was only 1 in (2.5 cm) in diameter, and it was just over 6 in (15 cm) in length—Newton remarked that it would 'discover as much as any three or four foot tube' and he forecast that similar reflectors 6 feet (1.8 m) in length would 'perform as much as any sixty or hundred foot [18–30 m] tube made after the common way'.

Although Newton was the first to build a reflecting telescope, the principle of the reflector had originally been suggested by James GREGORY in 1663. However, his design proved extremely difficult to build. Whereas Gregory's instrument relied on a parabolic primary mirror with a central hole and an elliptical secondary mirror, Newton's simply comprised a parabolic primary which reflected light onto a flat, tilted, secondary mirror (see GREGORIAN TELESCOPE).

A variation on the Gregorian design soon arrived with the introduction of the CASSEGRAIN TELESCOPE in 1672. This version used a convex mirror inside the focal length to reflect the light back through a central hole in the main

mirror. Today, it is the most common design for large reflecting telescopes. However, it was not until the mid eighteenth century that either the Gregorian or Cassegrain system was fully developed and became widespread. Cassegrain himself was never identified.

Despite these advances, large reflectors remained much more difficult to make than refractors, and half a century elapsed before they were able to compete on equal terms. No important discoveries were made with reflecting telescopes until the time of William HERSCHEL (1738–1822).

Herschel was renowned as the best telescope maker of his time. At his home in Bath, which he turned into a telescope workshop, Herschel experimented with different metal alloys in an attempt to find one with a high reflectivity, good resistance to tarnishing and reasonable ability to hold its shape during daily temperature changes. The best speculum metal alloy for his mirrors was found to be 79% copper and 21% tin. In 1778, he used this mixture for a 6.2 in (16 cm) reflecting telescope with a focal length of 7 ft (2.14 m), which he used for his second and third sky surveys. In 1782, a year after he used this instrument to discover URANUS, he demonstrated its superiority to the skeptical Astronomer Royal, Nevil MASKELYNE, at the Royal Observatory in Greenwich.

Upon receiving patronage from King George III, Herschel began to construct a giant 40 foot long (12 m) instrument with a mirror 48 in (1.2 m) in diameter. Completed in 1789, it remained the largest telescope in the world for more than half a century. On his second night of viewing with this monster, Herschel discovered the sixth moon of Saturn, ENCELADUS. Three weeks later, he discovered a seventh moon, MIMAS. Yet he was generally disappointed with his gigantic creation. It was clumsy to operate, while the mirror tarnished rapidly in the damp climate and distorted under its own weight.

Most of Herschel's discoveries were made with the 18.8 in (48 cm) reflector that he made in 1783. This instrument made a major contribution to the advancement of astronomy when his son, John, installed it at the Cape of Good Hope in 1834–8, and was able to survey the LARGE and SMALL MAGELLANIC CLOUDS, the center of our Galaxy, and the wonders of the southern skies.

The early nineteenth century saw a number of improvements in telescope optics. One of the leading telescope makers was the Director of the Physical and Optical Institute of Munich, Joseph von FRAUNHOFER (1787–1826), the inventor of the equatorial mounting. The most famous of his instruments was the Great Dorpat Refractor which F G W STRUVE set up at the Dorpat Observatory in Estonia in 1824. This 9.5 in (24 cm) refractor was used by Struve to discover more than 2 000 double stars.

Fraunhofer's invention of the diffraction grating and the later introduction of photography (first used in 1840) revolutionized optical astronomy and led to many discoveries. However, not until 1845 was Herschel's 48 inch telescope overtaken in size. Lord ROSSE's 6 ft (183 cm) aperture reflecting telescope contained the largest speculum metal mirror ever made, and had a light grasp more than double that of Herschel's instrument. Built at Parsonstown (now Birr) in Ireland, this instrument enabled Rosse to discover the spiral structure of certain nebulae (now recognized as galaxies), and to resolve others into star clusters.

Although Jean FOUCAULT (1819–68) introduced silver coating for glass mirrors, major astronomical instruments were being equipped with speculum metal mirrors as late as 1862. The last of the line was the Great Melbourne Telescope, whose 48 in (1.2 m) metal mirror required repolishing after a few years' use, and which was generally regarded as a failure.

Whilst reflectors were becoming the most widespread astronomical instruments, there was still considerable interest in pushing refractors to the limit. The culmination of this was the construction of the largest refracting telescopes ever built. The 36 in (0.9 m) instrument was installed at LICK OBSERVATORY in 1888, and was followed by the 40 in (1 m) telescope at YERKES OBSERVATORY in 1897.

The driving force behind the Yerkes project, George Ellery HALE (1868–1938), went on to promote the construction of two gigantic reflecting telescopes. The 100 in (2.5 m) Hooker Telescope on MOUNT WILSON, which was the largest in the world from 1918 until 1948, was the first instrument capable of seeing objects that formed early in the history of the Universe.

The 200 in (5 m) Hale Telescope on Mount PALOMAR, completed in 1948, was used for photographic studies which opened the way to further discoveries. Its giant primary mirror was a ribbed casting of Pyrex glass, while its parabolic surface was coated with a thin film of highly reflective aluminum. In 1976, an even larger 236 in (6 m) telescope was completed on Mount Semirodriki in the Caucasus region of the Soviet Union.

For a while, their great weight and the difficulties in casting such monolithic mirrors seemed to present an insurmountable barrier to the development of still larger telescopes. The primary mirror of the Hale Telescope weighs 13 tonnes, and was once considered the practical limit for telescope size.

While the giant reflectors were being used to study ever smaller fields of view, Bernhard SCHMIDT (1879–1935) was inventing a telescope which could take wide angle photographs. The first Schmidt camera, built in 1930, used a thin glass corrector plate to overcome spherical aberration. It soon spread around the world's major observatories and was incorporated in various hybrid designs such as the SCHMIDT–CASSEGRAIN.

The next major advance was the replacement of mechanical control systems by computers. In contrast to the Hale Telescope, which used huge motor-driven worm wheels controlled by a quartz crystal clock, the ANGLO-AUSTRALIAN Telescope, completed in 1975, set a new standard in computer control and pointing accuracy.

Computer control was also the key to the introduction of the multiple mirrors and segmented mirrors that broke the telescope size barrier. Leading the way was the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

MULTIPLE MIRROR TELESCOPE (MMT), which was built on Mount Hopkins in Arizona in 1977. By using six 72 in (1.8 m) mirrors in a circular array on an alt-azimuth mounting, the telescope's effective light-collecting area was equivalent to a single 172 in (4.5 m) instrument. One of these mirrors was used in the discovery of the first gravitationally lensed quasar.

The revolutionary MMT system was eventually replaced by a modern lightweight mirror with a honeycomb construction in 1998. Mirrors of this type consist of glass ribs between a thin, but rigid, concave mirror and a flat back plate.

In recent years, adaptive and active optics have been introduced in an attempt to compensate for image degradation caused by the atmosphere. Meniscus mirrors, that are too thin to support their own weight, and segmented mirrors can now be adjusted by computer-controlled servomechanical actuators so that they maintain their optimal shape and position at all times. Small adaptive mirrors may also be inserted in the light path of the telescope to correct atmospheric distortions. The EUROPEAN SOUTHERN OBSERVATORY's 138 in (3.5 m) New Technology Telescope was one of the pioneers in the development of such active and adaptive optics.

The largest mirrors in the world today, installed in the twin Keck telescopes on Mauna Kea, Hawaii, are made from 36 hexagonal 72 in (1.8 m) mirrors which fit together like bathroom tiles (see UNIVERSITY OF HAWAII INSTITUTE FOR ASTRONOMY). These segments effectively create a single mirror, 400 in (10 m) in diameter, with four times the collecting power of the Hale Telescope.

Another new technique that will eventually operate on the Keck telescopes is optical interferometry. Light from nearby, but separate, telescopes is combined so that the resulting image is equal to that received from a single giant telescope.

The European Southern Observatory started construction of the world's largest optical interferometer in 1996. The Very Large Telescope (VLT) in northern Chile will eventually combine the light from four 315 in (8 m) telescopes, producing a performance equivalent to that of a 630 in (16 m) instrument.

Meanwhile, advances in technology have also enabled scientists from the University of Arizona, Ohio State University and German and Italian astronomical research institutions to cast the largest single-piece mirror ever made. The LARGE BINOCULAR TELESCOPE at Mount Graham Observatory in Arizona will eventually be equipped with two 331 in (8.4 m) primary mirrors which have a thickness of only 1.1 in (28 mm) in the center and 35 in (894 mm) at the edge. These will provide an image comparable to that of a single 75 ft (23 m) telescope when construction is complete in 2002.

Such advances have, at least partially, nullified the advantages of placing telescopes in space. However, despite its relatively small 95 in (2.4 m) mirror, the HUBBLE SPACE TELESCOPE (launched in 1990) continues to return some of the highest resolution optical images of faint galaxies located billions of light years away. An 8 m class replacement with a folding mirror, known as the Next Generation Space Telescope, is in the pipeline for a 2008 launch(see SPACE INSTRUMENTATION: NEXT GENERATION SPACE TELESCOPE). Multiple space telescopes using optical interferometry, which will be capable of imaging Earth-size planets around nearby stars, are envisaged for the following decade.

Telescopes of the Future

New telescopes, new detectors and new regions of the electromagnetic spectrum have often revealed totally unsuspected aspects of the universe. Consider the careful spectroscopic observations of nebulae started around 1912 by Vesto Slipher, using the modest 24 in (61 cm) telescope of Lowell observatory. The recession velocities of thousands of kilometres per second that he found were completely unexpected and, only in 1917 did Willem de Sitter begin to understand them as galaxies in an expanding universe. Dark matter, a still unidentified form that outweighs all normal matter in the universe and controls the condensation of matter after the big bang, was discovered by Fritz Zwicky and Vera Rubin during spectroscopic observations to weigh galaxies. The rapid motions reflected a gravitational pull too large to be accounted for by ordinary matter in stars and interstellar material. The microwave background radiation, the cooled light of the big bang itself, was completely unforeseen by its Nobel-prize-winning discoverers, Arno Penzias and Robert Wilson (although not by others).

What common threads may be found in these and the many other unexpected discoveries in astronomy? Very often the observers were pushing new equipment to its limits to accomplish a highly focused goal unrelated to the actual discovery. Slipher was hoping that the diffuse nebulae might turn out to be nearby planetary systems in formation. Zwicky and Rubin were using the largest telescopes to see fainter objects than ever before. Penzias and Wilson were testing a highly sensitive new type of radio telescope for communications.

More generally, unforeseen discoveries are made when the range of observations is enlarged. This happens whenever new parts of the electromagnetic spectrum are opened for observation. New vistas are also opened when larger telescopes or better detectors allow us to reach fainter objects or bigger samples or to study brighter ones in more detail or with better time resolution.

A major new development in astronomy that is likely to drive new instruments in the coming decades is the exploration of exoplanets, the planets of other stars. The existence of other living worlds like our own has been the subject of speculation for centuries. However, telescopes have not been powerful enough to discern extrasolar planets. In the solar system, the Earth already occupies the prime location and our neighbours appear too hot or too cold. Now at last, with clear evidence that giant planets exist around other stars, we have the technical capability and the incentive to build radical new telescopes to study them. With them we should be able to find planets even as small as Earth and to search their spectra for the biochemical signs of life. The potential for unforeseen discovery is enormous. The first discoveries have already revealed completely unpredicted phenomena: planets of Earth's mass orbiting a pulsar and planets with the mass of Jupiter orbiting closer to their stars than does Mercury to the Sun, a place far too hot for them to form.

Ground telescopes come of age

During the 40 yr after the Palomar 200 in (5 m) telescope came into operation, the power of optical telescopes increased enormously, even though no significantly bigger instrument was built. The gains were made by improving detector sensitivity 100-fold to reach the fundamental limit set by photon noise, by extending detector sensitivity into the infrared and by multiplexing so that dozens or hundreds of objects could be analysed at once. However, as these advances have reached their limits, the past decade has seen the construction of a new generation of much larger telescopes. Starting with the two 10 m Keck telescopes, there are now around a dozen of size 6.5–10 m in operation or under construction. With such an increase in collecting area, some profound unforeseen discoveries can be expected. This will be especially true when these telescopes are able to remove atmospheric blurring and are linked together as interferometers. Until now, astronomers have had to choose between small-aperture telescopes in space that are free from blurring (the Hubble Space Telescope or HST) or large-aperture telescopes on the ground with blurring. Adaptive optics is a new technique that will give both advantages at once. In fact, because the natural limit to resolution set by diffraction improves in proportion to aperture, the bigger ground telescopes will be several times sharper than HST.

The key element in adaptive optics is a mirror whose shape can be altered rapidly in response to the measured atmospheric distortion. By giving the mirror equal but opposite distortion, the original image sharpness is restored. It has been difficult to make the measurement and correction fast enough to keep up with the constantly changing turbulence, but today's detectors and computers make it possible. Correction of bright objects has already been accomplished and in a few years we should start to see sharp images of even the faintest objects corrected at infrared wavelengths. When a target itself is too faint to allow fast measurement of atmospheric distortion, an artificial star created by a laser searchlight may be used as a surrogate. Experimental laser systems are in operation, although the combination of exquisite tuning and high power needed to excite scattering very high in the atmosphere is proving elusive.

Once adaptive optics is in place, another technique to increase the scope for discovery becomes possible. This is interferometry, long used by radio astronomers, which relies on combining the waves from separate telescopes. By measuring the strengthening and weakening of intensity as the crests and troughs reinforce or cancel out, images with greatly increased angular resolution are obtained. Interferometry can be extended to optical

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

wavelengths for very high-resolution imaging, but sensitivity is poor unless all the waves from each dish add together coherently. In the presence of atmospheric distortion, coherent addition is possible only when very small apertures are used. However, once the full apertures of the large telescopes are corrected with adaptive optics and used as interferometer elements, very faint objects will become accessible.

All of the largest telescopes have been built as multiple units in anticipation of interferometry: Europe's Very Large Telescope (VLT) consists of four telescopes, while the Keck and Large Binocular Telescope (LBT) each have two (figure 1). Because the LBT mirrors are on a common mounting and closely spaced, as an interferometer it will act like a 22 m telescope with a resolution of 10 marcsec and high infrared sensitivity to complex, faint sources over a wide field of view. It will be able to find and analyse the thermal spectrum emitted by self-luminous giant planets, younger versions of our own Jupiter. The VLT and Keck telescopes are separately mounted and widely spaced (up to 100 m) for resolution as high as 2 marcsec over a field of 1 arcsec, but at the price of lower sensitivity and some ambiguity in image structure. They should be able to resolve those Jupiter-sized exoplanets mentioned above that are so close to their stars that they are red hot.

Now that the construction phase of the current generation of big telescopes is winding down, their designers are looking at ways to build bigger optical telescopes. In California, a single telescope of 30 m diameter (the California Extremely Large Telescope) is being studied; in Europe, one of 100 m (the OverWhelmingly Large telescope). Arizona's focus is on an imaging interferometer with two 20 m moving telescopes, the 20/20 telescope. With adaptive optics and interferometry, their sensitivity and resolution can potentially far outstrip what we have now. The tasks foreseen for such telescopes include observations of the very early universe at much higher resolution and sensitivity than possible with HST and the detailed spectroscopic study of Jupiter-like exoplanets. If the closest stars have Earth-like planets, they should be visible in long exposures with the 20/20 telescope. In addition, the prospect of unforeseen discovery is a powerful motivator.

New discoveries are likely not only from such larger telescopes and higher-resolution images but also from automated analysis of deep-sky images. In the past, photographic plates from 1.2 m telescopes covering 6º of the sky on a side have provided a rich source of data. Electronic detectors are now greatly increasing the accuracy, sensitivity and spectral range of these measurements. Two digital all-sky surveys with 1.2 and 2.5 m telescopes are in progress now, with charge-coupled device detectors for optical wavelengths in a mosaic of area 0.1 m^2 and near-infrared detectors of

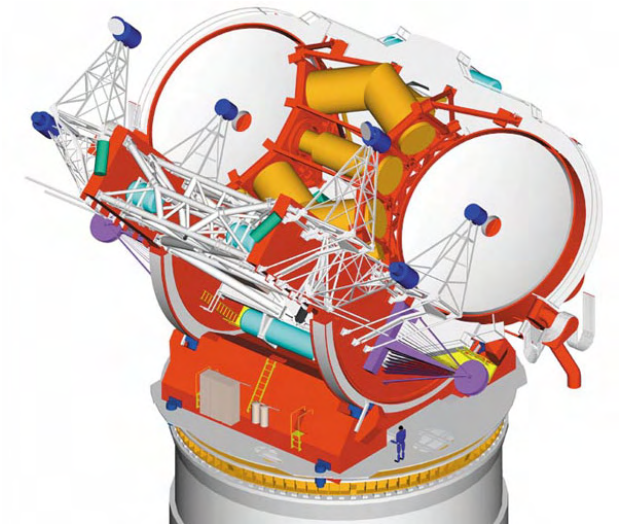

Figure 1. The LBT, with two 8.4 m mirrors side by side. (Drawing by European Industrial Engineering, Mestre, Italy.)

0.001 m^2. The coming decade should see the construction of the 8 m Large Synoptic Survey Telescope with 3º field (0.5 m m^2 detector illuminated at *f*/1.25). The data rate will be prodigious, with the night sky repeatedly mapped every four clear nights, creating 10 terabytes of data per map. Two key goals will be finding and measuring the orbits of asteroids as small as 300 m that could hit the Earth and mapping the spatial distribution of dark matter on large scales. Dark matter is detected through the small but systematic distortion it induces in the shapes of background galaxies. The data reduction for these tasks is big, but well defined. The challenge for computer gurus will be to spot the unforeseen—for example, new types of erratic variable objects or subtle large-scale correlations in data.

The limitless potential of space

Despite the evolution of much more powerful ground telescopes, space still holds unique and fundamental advantages. Complete freedom from atmospheric distortion in space will remain a major asset. Even when laser guide stars are used for adaptive correction on the ground, a nearby background star is still needed to sense overall jitter of the sharpened image. Stars are dense enough for infrared imaging over most of the sky, but optical imaging, which demands more accurate and faster stabilization because of the shorter wavelengths, will be restricted to fields near a bright star. Tomographic, three-dimensional mapping of atmospheric turbulence with multiple laser guide stars may be able to relieve this optical restriction and open wide-field correction. Although possible in principle, this will be very challenging.

The second unique capability of telescopes in space is for observations in the blocked ultraviolet and infrared spectral regions. Even where it transmits in the infrared,

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the atmosphere is bright from heat and molecular emission. Additional background heat comes from the ground telescope optics themselves, which cannot be cooled because that would cause them to frost. Space telescopes can be made extremely cold, for a million times reduction in sky background.

The current generation of space telescopes has already shown how these advantages can be exploited. HST records wide-field optical images typically 10 times sharper than for uncorrected ground-based telescopes and reaches far into the vacuum ultraviolet. Its capability has been steadily improved by astronauts. For example, a new instrument was added to extend imaging and spectroscopic capability to the near infrared, where the natural sky background from sunlit interplanetary dust is much darker than on Earth. HST is likely to remain the only large optical telescope in space for astronomy for at least the next decade. Its dominance will be weakened by a strong challenge from ground telescopes, but perhaps that will allow time for more speculative use that could lead to unforeseen discovery.

HST's mirrors are too warm to be useful further into the infrared, where on the ground the atmosphere completely blocks transmission. Here three other space telescopes, the Infrared Astronomical Satellite, the Cosmic Background Explorer and the Infrared Space Observatory, all cooled with liquid helium to within a few degrees of absolute zero, have revealed the very cold universe. New discoveries can be expected from the Space Infrared Telescope Facility (SIRTF), a new helium-cooled telescope with 0.85 m aperture and more advanced detectors, which is scheduled for launch in 2002. It will reach to 160 μm wavelength.

Beyond these telescopes, the potential for future space astronomy is limitless. In principle, arbitrarily high sensitivity and resolution can be achieved at any desired wavelength by making the telescope large, accurate and cold enough. Space is an ideal environment, because not only is atmospheric degradation removed but so also are gravity and wind. This is a huge advantage because, under such forces, big objects bend more than small ones, whereas, no matter how big a telescope is made, the mirror surface accuracy cannot be relaxed if the waves are to be reflected to a sharp focus.

What might a future telescope look like, built for operation in orbits far from the Earth where distorting forces are minimal? The actual working part of a telescope mirror is the top layer of the reflecting surface, which is only a few hundred aluminum or silver atoms deep. Thus there is the possibility in space of using extremely thin membrane mirrors covering hundreds or thousands of square metres, if a way can be found to hold the shape. One way is to stretch a membrane flat from the edge and then to curve it very slightly by electrostatic force. An experimental telescope made in this way from a membrane 600 nm thick (a few thousand atoms) was used to record the image shown in figure 2. While very small, this mirror paves the way for larger-membrane telescopes, with tests planned first on the ground and then in space.

For such gossamer telescopes in space, the main disturbance comes from sunlight, which both warms spacecraft and pushes them. Light pressure was strong enough to disturb noticeably the orbit of the 100 ft (30.5 m) Echo balloon satellite launched in 1960 (only 4 yr after Sputnik) and would blow a 600 nm thick membrane right out of the solar system. Gossamer telescopes thus would have to be shielded from sunlight, but the shields must be lightweight too, and held off the telescope somehow, for solar pressure would push a freely orbiting shield into collision with the shielded mirror. Future gossamer telescopes may look more like sailing ships than the telescopes we now know.

Suppose at some time we find a planet that shows clear chemical evidence of life. Could we image it? The largest space telescopes we can conceive do not use mirrors at all and are extremely heavy, focusing light by gravitational bending. Figure 3(*a*) shows how multiple images of the same very distant galaxy are formed and distorted into magnified arcs by an intervening blob of dark matter, traced out by the brighter galaxies held in its gravitational field. The distortion was removed to yield the image shown in figure 3(*b*). Our deepest views of the distant universe will probably rely on finding chance alignments like this to aid our biggest ground and space telescopes. There is no chance that a nearby black hole will lie conveniently in front of and magnify an

interesting planet, but we could use the Sun as a gravitational lens by sending a detector out of the solar system in the opposite direction to the planet. Once it is far enough away, more than 600 times the radius of the Earth's orbit, light from the planet bent around the Sun will be brought to a focus, forming a large image. Taking a detector to such distance may sound difficult, but it is still far easier than interstellar travel to even the nearest star, 1000 times further away.

The next space telescopes

The astronomy community has identified two key scientific goals to shape the development of more powerful space telescopes. One is to probe deeply the highly redshifted early universe, of which we have caught the first glimpse with HST. It is best observed in the virtually unexplored 2–5 μm region of the electromagnetic spectrum where the natural sky background is darkest. The other goal is the exploration of other planetary systems, with particular emphasis on looking for Earth-like planets, which will be restricted to only the very nearest stars from the ground. This is best attempted from space by detection of the infrared heat emitted by planets (10–20 μm) rather than the starlight they reflect. Their thermal emission is much brighter relative to the star, and the spectroscopic signatures of key diagnostic molecules, water and ozone, could be very strong, as they are in Earth's spectrum. Ozone would be of enormous interest, as in our atmosphere it is of biological origin.

Remarkably enough, both these major scientific objectives involve similar technical advances in the previously neglected shorter wavelengths of the thermal infrared spectrum. Both need mirror temperatures in the range 30–100 K, which should be reachable without expendable refrigerants by carefully shielding against solar heating and by lofting so far from the warm Earth that it appears no bigger than the Moon. Mirrors even larger than HST's 2.4 m are desirable in both cases, once the technology can be developed to make them. The extreme lightweighting of membrane structure is not yet needed, but the passive, rigid mirrors that are the current standard for all space telescopes will no longer be adequate. We will have to learn how to transfer to space the key technology that has made the new, big ground telescopes possible—namely, active control to correct distortion caused by mechanical or thermal disturbance. Ground telescopes automatically check star images as fast as every minute and make appropriate corrections of alignment and mirror distortion to maintain optical quality.

Detailed studies are being made of a telescope envisaged to succeed HST, the Next Generation Space Telescope (NGST), with a primary mirror 8 m in diameter operating at a temperature of 50 K (figure 4). Because the practical limit for a telescope launched in one piece is 4–6 m, depending on the size of future rocket fairings, it would be necessary to build the mirror and telescope in space. Planning has so far focused on automatic deployment from an unmanned payload. The whole spacecraft will have to weigh a lot less than HST, even though the telescope has ten times the mirror area, if it is to be carried a million miles from the Earth.

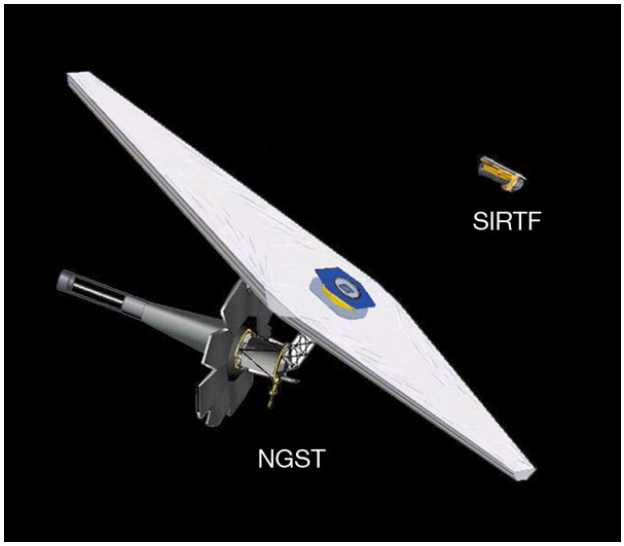

Figure 4. Evolution of infrared space telescopes. Shown to relative scale are SIRTF, a 0.85 m cryogenic telescope to be launched in 2002, and a concept for the 8 m NGST. Both will orbit far from the Earth, with thermal shields on the Sunward side.

The mind-stretching NGST goal has been a most effective way to focus research in universities, industry and government centres. New technologies have been identified and development work is going on in many areas. As an example, Jim Burge at the University of Arizona has been devising ways to take the mature technology used at the Mirror Laboratory for 8 m glass mirrors for the ground (weighing 18 tons) and produce an 8 m mirror in space weighing less than 1 ton. The idea, demonstrated 4 yr ago at the 0.5 m scale, is to keep only the first couple of millimeters of the reflecting glass surface and replace the rest with an ultralightweight carbon fibre truss. Figure 5 shows the 2 m diameter, 2 mm thick facesheet that will be connected to a truss by 166 active screw actuators. The whole prototype mirror assembly is 1/20 the weight of the 2.4 m HST mirror.

Although ultralightweight active mirrors are vital, they are but one of a range of challenging new technologies being studied for NGST. For example, passive cooling to cryogenic temperature is new and in order to cool an 8 m telescope to 50 K the sunshield shown in figure 4 must be the size of a tennis court. It must be such a good insulator that less than 1/1000 of the heat from the full blast of the Sun is allowed to leak through to be radiated into space. If, as currently conceived, the huge, flimsy NGST structure and sunshade are to deploy automatically, how does one test it beforehand in the Earth's gravity to be sure it will work?

An even more ambitious target has been set for the investigation of Earth-like planets. The basic approach is to detect their heat with a special form of interferometer

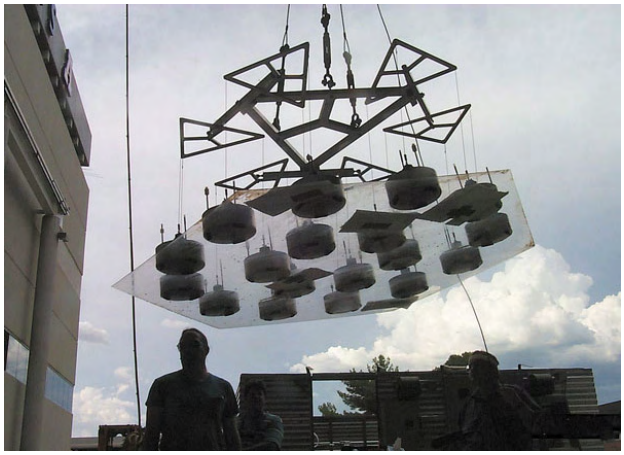

Figure 5. A 2 m hexagonal concave glass mirror is lifted clear after separation from the support on which it was thinned and polished. It is 2 mm thick and weighs just 30 lb (13.6 kg). (Image courtesy of J. Burge.)

in space. The beams from the different mirrors must be brought together with an accuracy of a nanometer despite tens of metres separation. Such accuracy is needed to fully cancel out the star's electromagnetic waves by maintaining the crests and troughs exactly out of phase, while leaving the planet image intact, a technique known as nulling interferometry. A mission called Terrestrial Planet Finder (TPF) is envisaged to explore not just the nearest few stars but over a hundred Sun-like stars out to a distance of 50 ly. This would require four or more cryogenic 4 m telescopes spread out over 100 m. They could be connected mechanically or orbited separately in formation.

Reliable and affordable solutions

Now that these scientific goals and the range of technical challenges required to accomplish them are identified, we must find the best path to proving solutions that will work reliably and will be affordable. Perhaps the best approach is an evolutionary process based on intermediate missions, each aimed at three goals: first, testing out one or more of the key technologies needed for the full-scale NGST and TPF missions; second, proving that new technology can be delivered affordably; third, using it for astronomical exploration.

The last requirement is crucial. The only way to find unanticipated flaws is by attempting challenging observations in space. Because each of the multiple technological developments for NGST and TPF is profound, any one of them alone could be used to open new scientific frontiers. Consider what might be done relatively soon. Even an old-fashioned, rigid telescope, if taken far from the Earth and passively cooled to 30 K, could open a new window to the high-redshift universe. A warm, 4 m, ultralightweight telescope could test autonomous active control for high-contrast images and

Dirac House, Temple Back, Bristol, BS1 6BE, UK

see further than HST. A short nulling interferometer with proven, 1 m class cryogenic mirrors in a distant cold orbit could already find and obtain images and spectra of any Earth-like planets around the very nearest stars.

Such missions could also be configured to test solutions to what may be the most difficult problem, namely how to endow remote, cold observatories with HST-like longevity and productivity. If there were no possibility of repair and refurbishment, any big space telescope of HST-level or greater complexity would inevitably be risky and become dated. Space Station provides a natural solution, as a base where complete large telescopes and spacecraft could be assembled and tested in the gravity-free space environment. With solar cells deployed, the structure would be pretty flimsy, but a low-thrust tug could, in a few months, gently push it to the cold, stable point a million miles from Earth. By the same means, it could be brought back for repairs when necessary. The alternative is to leave the observatory in the cold and to send out cryogenic robots to fix it *in situ*.

These are exciting times. While we sort out the challenges of space telescopes, a golden era of discovery should come from the much higher resolution and sensitivity and data throughput of big ground telescopes and interferometers. Then from space we should be ready to open wide the relatively unexplored infrared spectrum, which holds such promise for discovery, from the furthest reaches of the universe to planets of the nearest, ordinary stars.

Telescopium

(the Telescope; abbrev. Tel, gen. Telescopii; area 252 sq. deg.) A southern constellation which lies between Ara and Indus, and culminates at midnight in early July. It was introduced to commemorate one of the long 'aerial telescopes' used by the Cassinis at the Paris Observatory by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2, and it originally included stars from the neighboring constellations of Ophiuchus (which was larger then than it is now), Scorpius, Corona Australis and Sagittarius, but is now restricted to stars to the south of the last two constellations.

A small, inconspicuous constellation, the brightest star in Telescopium is α Telescopii, magnitude 3.5. There are no other stars brighter than magnitude 4.0. Interesting objects include RR Telescopii, a nova-like star (range 6.5–16.5) and the only one recognized as a periodic variable before its slow (1600 day) rise to seventh magnitude in 1944, and NGC 6584, a ninth-magnitude globular cluster.

Tempel, Ernst Wilhelm Leberecht (1821–89)

German astronomer, born in Nieder-Kunersdorf, near Löbau, in Saxony; trained as a lithographer, he settled in Italy, and took to amateur astronomy, at first using the balcony of a Venetian palace and discovering a comet in 1859. Discovered the reflection nebula around Merope in the Pleiades. Became astronomer at Marseilles Observatory, discovered eight comets (including the comet associated with the Leonids) and five minor planets. Expelled in 1871 from France he returned to Italy, working at the Brera Observatory, Milan, adding to his total score of 13 comet and 6 minor planet discoveries, and became director of the Arcetri Observatory, where he worked with decrepit equipment on nebulae.

Temperature Scales

Three different scales for describing temperature are in common use, the Celsius scale, the Kelvin scale and the Fahrenheit scale.

On the Celsius scale, which was devised in 1742 by the Swedish astronomer Anders Celsius (1701–44), temperatures are expressed in degrees Celsius (°C), where one Celsius degree is one-hundredth part of the difference in temperature between the freezing point and the boiling point of water (at standard sea-level atmospheric pressure). Because it is based on dividing that temperature range into 100 parts, it is also known as the centigrade scale. Temperatures below 0°C are given negative values.

On the Kelvin, or absolute, temperature scale, which was named after the British physicist Lord Kelvin (William Thomson 1824–1907), the unit of temperature is the kelvin (K), one kelvin being equal in magnitude to one degree Celsius. The zero of the kelvin scale is absolute zero, the temperature at which, classically, the motion of atoms would cease completely and which, therefore, is the lowest possible temperature. Absolute zero, 0 K, corresponds to a temperature of −273.15 °C. Because the kelvin is equal in magnitude to the Celsius degree, a temperature expressed in kelvin is equal to the temperature in degrees Celsius plus 273.15. Thus, for example, the freezing point of water (0 °C) is equal to (0 + 273.16) = 273.15 K and the boiling point of water (100 °C) is equal to 373.15 K. To convert from °C to K, add 273.15; to convert from K to °C, subtract 273.16. Because the Kelvin scale is directly related to the physical meaning of temperature, it is the most appropriate scale to use in a scientific context. The kelvin is the SI unit of temperature (the unit of temperature in the International System of Units) and is defined more specifically as 1/273.16 of the thermodynamic temperature of the triple point of water.

Although obsolescent, the Fahrenheit scale, which was devised by the German instrument-maker Gabriel Fahrenheit (1686–1736), is still used in some contexts. On the Fahrenheit scale, the unit of temperature is the degree Fahrenheit (°F), which is 1/180 of the difference in temperature between the freezing and boiling points of water. The freezing point of water is 32 °F and the boiling point of water, 212 °F. Since 180 Fahrenheit degrees corresponds to 100 Celsius degrees, one Fahrenheit degree is equivalent to 100/180 (=5/9) of one Celsius degree. To convert a temperature in °C to a temperature in °F, multiply by 9/5 and add 32. For example, 100 °C = (100 × 9/5) + 32 = 180 + 32 = 212 °F. Conversely, to convert from °F to °C, subtract 32 and then multiply by 5/9 (for example, 212 °F = (212 − 32) × (5/9) = 180 × (5/9) = 100 °C.

Terminator

The line marking the boundary between the day and night sides of a solar system object, as seen from the Earth or from a spacecraft. As the relative positions of the Earth, the Sun and the object shift, the proportion of the object's sunlit side visible from the Earth changes and the terminator moves across the object's disk. The terminator thus determines the object's phase. From the Earth, the Moon, Mercury, Venus and Mars show terminators. The Moon's rough terrain gives its terminator a jagged appearance, and sometimes elevated features just to the night side of the terminator are visible, obliquely illuminated by the Sun.

Terrestrial Coordinate Systems and Frames

A terrestrial reference system (TRS) is a spatial reference system corotating with the Earth in its DIURNAL MOTION in space. In such a system, the positions of points anchored on the Earth's solid surface have coordinates which have only small variations with time, as a result of geophysical effects (tectonic or tidal deformations; see TECTONICS, EARTH'S INTERIOR, TIDES). A terrestrial reference frame (TRF) is a set of physical points with precisely determined coordinates in a specific coordinate system (Cartesian, geographic, mapping, ...) attached to a TRS. Such a TRF is said to be a realization of the TRS.

Concepts and terminology

These concepts were redefined extensively in the 1980s by the astronomical and geodetic communities (see for instance Kovalevsky *et al* 1989).

Ideal terrestrial reference systems

An ideal TRS is defined as a three-dimensional reference frame (in the mathematical sense) close to the Earth and corotating with it. In the Newtonian background, the geometry of physical space considered as a Euclidean affine space of dimension 3 provides a standard and rigorous model of such a system through the selection of an affine frame (O,E). O is a point of the space called the origin. E is a vector base of the associated vector space. The currently adopted restrictions on E are that it is orthogonal with the same length for the base vectors. Moreover, one adopts a direct orientation. The common length of these vectors is called the scale of the TRS and the set of unit vectors collinear with the base its orientation:

$$\lambda = \|\vec{E}_i\| \qquad i = 1, 2, 3.$$

Two major types of TRS are in use.

- In the local or topocentric ones the origin is located on the Earth's surface and the orientation uses the local vertical direction for the Z axis. In general, Cartesian coordinates or plane coordinates are used.
- In the geocentric ones the origin is close to the geocenter and the orientation is equatorial (the Z axis is the direction of the pole). In this case, Cartesian coordinates, geographical coordinates or plane (map) coordinates are used (see GEOCENTRIC COORDINATE SYSTEM).

The first type is used for technical purposes (laboratory experiments, local topography and surveying, ...) while the second is the current practice for astrometry or global geodesy. In the case of geocentric systems, one further distinguishes two subtypes, depending on the method used to establish and realize such systems (classical terrestrial or space techniques).

- The first is true geocentric which means that realizations will be close to the geocenter (a few meters at the beginning of satellite geodesy, now a few centimeters; see SPACE GEODESY) and the zero MERIDIANS of the equatorial orientations will be almost identical (currently expressed using the name of Greenwich, for historical reasons).
- The second is quasi-geocentric (this is a better term than non-geocentric, which may be too easily confused with topocentric) for systems established with terrestrial geodetic techniques usually using a fundamental station. In such cases, the origin may be separated from the geocenter by several hundred meters. Notice also that these systems currently use a zero meridian linked to some astronomical observatory and therefore should be realigned with the conventional Greenwich origin by adopting a longitude for this zero meridian with regard to Greenwich. For instance, in Europe, several conventional origins are still in use for mapping purposes (Paris, Rome, Madrid, ...).

Under these restrictions, the general transformation of the Cartesian coordinates of any point close to the Earth from any one TRS to any other one will be given by a three-dimensional similarity (T is a translation vector, λ a scale factor and R a rotation matrix):

$$X^{(1)} = T_{1,2} + \lambda_{1,2} R_{1,2} X^{(2)}.$$

This concept can be generalized in the framework of a relativistic background model such as Einstein's GENERAL THEORY OF RELATIVITY, using the spatial part of a local Cartesian frame (Boucher 1986).

Conventional terrestrial reference system

Such a system designates the set of all conventions, algorithms and constants which determine the estimation of coordinates of points in a specific ideal TRS.

Conventional terrestrial reference frame

A conventional TRF is defined as a set of physical points with precisely determined coordinates in a specific coordinate system as a realization of an ideal TRS. Two types of frames are currently distinguished (this is also valid for celestial references), namely dynamical or kinematical ones, depending whether a dynamical model is applied in the determination process of these coordinates or not.

Examples of dynamical TRF are ephemerides of artificial satellites. This approach is currently widely used: EPHEMERIDES of navigation satellite systems, such as the Global Positioning System (GPS), or ephemerides of satellite radar altimeters used to derive sea surface heights in a well-realized TRS (Topex Poseidon, or the forthcoming Jason 1).

However, kinematical TRFs are still the most-used type, especially with networks of physical points on the topographic surface of the solid Earth for which numerical values of coordinates are estimated. We can identify three major purposes for the use of such a TRF.

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

- In a metrological approach it is a physical realization of a TRS, in the way that standards realize units.
- In a user-oriented approach the points can be used to determine other points (densification or expansion). This is a major role for networks.
- In a geophysical approach the points are deformation sensors of the solid Earth's surface. This has the double value of providing data for geophysical knowledge and improving the estimation strategy for positions by using better geophysical models.

Networks can be global if they cover more or less sparsely the whole Earth or regional if they cover a region of the Earth, such as a continent or a country. They can also be considered according to their type of coordinate system and are then specifically qualified by the following:

- horizontal if using plane coordinates or geographical latitudes or longitudes;
- vertical if using heights;
- three-dimensional if using Cartesian or Geographical coordinates (with ellipsoidal heights);
- astronomical, if using astronomical latitudes and longitudes.

Another interesting criterion is the nature of the physical points.

- A classical network uses passive markers or benchmarks, available as either a station point or a target for the user's measurements.
- A permanent network consists of beacons or receivers operating permanently and providing data suitable for precise determination of their position. This is the typical case for space geodetic ground tracking systems.
- In active networks a permanent station provides additional information (on their precise position) enabling users to determine positions of other points in the same TRS. Such current additional data are the raw measurements performed by the station or derived from differential corrections such as DGPS. Such data are available in real time or not, depending on various communication media.

Realizations of the terrestrial reference systems: past, present and future

Until 1960, the epoch of the availability of the first artificial satellites of the Earth, the terrestrial reference systems were realized at two levels. The primary realization was *de facto* obtained by the set of the various astronomical observatories which observed the Sun, Moon and planets, as well as star positions. This was therefore an astronomical network in which the longitudes were unified only progressively, national observatories keeping for a long time their own origin. At the end of the 19th century, an international origin was adopted, initially based on the ROYAL OBSERVATORY, GREENWICH in the UK.

The secondary realizations were developed through geodetic activities around the world, mainly driven by mapping needs. Since the birth of the triangulation method attributed to GEMMA FRISIUS in 1533, geodetic control by triangulation (and precise levelling in the 19th century) progressively covered the part of the Earth's surface not occupied by oceans or seas. While the shape of these networks was provided by angle and distance measurements, their orientation and absolute position with regard to the Earth's body were obtained by astronomical measurements (latitude, longitude and azimuths). Consequently, each set of geodetic coordinates (either geographical or plane) of the control points belonging to a given geodetic network constituted a specific TRF. Such networks were of local, national or even continental extension. The progressive unification of these regional networks was developed at the end of the 19th and beginning of the 20th century by the establishment of international junctions (Channel, Baltic Sea, Gibraltar, . . .) and the readjustment of control networks of continental size (North American Datum, European Datum, . . .). (For more details, see Boucher (1989).)

In 1899, the International Latitude Service was established and modified into the International Polar Motion Service (IPMS) in 1964. Meanwhile, the Bureau International de l'Heure (BIH) was created in 1912 to realize an international time scale, which also required the Earth orientation parameters (EOPs) to be determined.

In the late 1950s, new methods using space techniques appeared providing extensive information on the gravity field and EOPs as well as tracking station positions. These space techniques progressively superseded classical astrogeodetic methods. A few years of international cooperation (MERIT campaign; see Wilkins 1988) started an intercomparison of these various techniques (VLBI, laser ranging to satellites or to the Moon, radio techniques). During this campaign, a fundamental change appeared as the primary TRF started to be realized by the three-dimensional Cartesian positions of tracking stations, replacing astronomical coordinates (Boucher and Feissel 1984). As a result, the INTERNATIONAL ASTRONOMICAL UNION (IAU) and the International Union of Geodesy and Geophysics (IUGG) decided to replace BIH and IPMS by a new service, the International Earth Rotation Service (IERS), established in 1988. Its mission was to provide to the worldwide scientific and technical community reference values for the EOPs and reference realizations of internationally accepted celestial and terrestrial reference systems.

The IERS is at present the structure in charge of realizing, using and promoting the International Terrestrial Reference System (ITRS) as defined by the IUGG resolution No 2 adopted in Vienna, 1991.

The ITRS definition fulfils the following conditions.

- It is geocentric, the center of mass being defined for the whole Earth, including oceans and atmosphere.

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

- The unit of length is the meter (SI). This scale is consistent with the TCG time coordinate for a geocentric local frame, in agreement with IAU and IUGG (1991) resolutions (see TIME SCALES: TERRESTRIAL). This is obtained by appropriate relativistic modeling.
- Its orientation was initially given by the BIH orientation at 1984.0. The IERS Reference Pole (IRP) and Reference Meridian (IRM) are consistent with the corresponding directions in the BIH directions within $\pm 0.005''$. The BIH reference pole was adjusted to the Conventional International Origin (CIO) in 1967; it was then kept stable independently until 1987. The uncertainty of the tie of the IRP with the CIO is $\pm 0.03''$.
- The time evolution of the orientation is ensured by using a no-net-rotation condition with regard to horizontal tectonic motions over the whole Earth.

See the IERS Conventions (1996) for a detailed description of ITRS.

Realizations of the ITRS are produced by the Terrestrial Frame Section of the IERS Central Bureau under the name International Terrestrial Reference Frames (ITRF); these consist of lists of coordinates (and velocities) for a selection of IERS sites (tracking stations or related ground markers) obtained by combination of several space techniques, currently by VLBI, LLR, GPS, SLR, and DORIS. General documentation on terrestrial reference systems and frames is available on WWW: http://lareg.ensg.ign.fr/ITRF/.

The ITRS can be connected to the International Celestial Reference System (ICRS) by use of the IERS EOPs. ITRS is also used as a reference for specific products which include TRF data. For instance, the World Geodetic System (WGS) program uses ITRS; in particular the most recent system, WGS84, is carefully linked to ITRS (Malys and Slater 1994)

Terrestrial Planets

A collective term for the major planets Mercury, Venus, Earth and Mars, which are all 'Earthlike' in being of the order of 10 000 km in diameter, with densities of roughly 5000 kg m^{-3}, having a rock/metal composition with a solid surface, and possessing a small number of satellites or none at all. Pluto was once counted as a terrestrial planet, but once its low size and mass became apparent it was excluded from this category. The Earth is the largest and most massive of the terrestrial planets. Mercury, the smallest, is also the densest, and possesses the most rarefied atmosphere. The densest atmosphere, with a surface pressure 90 times the Earth's, is on Venus. Mars is the least dense terrestrial planet.

Compare: giant planets.

Tethys

A mid-sized icy satellite of Saturn, discovered by Giovanni Cassini in 1684. Its diameter is 1060 km, and its orbital distance from Saturn is 295 000 km. The parts of Tethys imaged in the Voyager missions show a variety of terrains with different crater densities. The heavily cratered side contains a large impact feature, the 440 km diameter basin Odysseus, a 'relaxed' structure with signs of an inner mountain ring. On the hemisphere opposite Odysseus is a lightly cratered plain cut by Ithaca Chasma, a huge valley system of multiple faults over 100 km across at its widest and around 1000 km long, whose formation may be linked with the impact that produced Odysseus. The plains are a consequence of resurfacing in the distant past. The satellite's overall density is 1000 kg m^{-3}, indicating a composition largely of water ice. The orbit is shared with two co-orbital satellites, Calypso and Telesto.

Thémis

The Thémis 'Telescope Heliographique pour l'Étude des Instabilites Magnetiques sur le Soleil', telescope has been built and is operated in the frame of a cooperation between the CNRS-INSU (Conseil National de la Récherche Scientifique-Institut National des Sciences de l'Univers, France) and the CNR (Consiglio Nazionale delle Ricerche, Italy).

The telescope is located at the 'OBSERVATORIO DEL TEIDE' in Tenerife (Canary Islands, Spain) which is operated by IAC (INSTITUTO DE ASTROFÍ SICA DE CANARIAS) under the International Agreements on Astrophysics between Spain and many other countries. The site coordinates are: longitude 16 30 31.6, latitude 28 18 13.8, altitude 2456 m above sea level. A total of about 15 permanent staff are working at Thémis, in cooperation with several French and Italian research groups (DASOP-Meudon and DT-INSU in Paris, Midi-Pyrenees in Toulouse, Arcetri Observatory and University in Florence, University Tor Vergata in Rome).

Thémis is a 90 cm diameter Ritchey–Chrétien altazimuthal telescope conceived to observe solar magnetic structures in the visible spectrum with high (spatial, spectral and polarimetric) resolution. The design of the telescope has been realized to minimize the instrumental polarization.

The main observing modes offered by Thémis are MTR (Multi Lines Spectroscopy), MSDP (Multi Channel Subtractive Double Pass Spectroscopy), both with or without polarization analysis, and IPM (Italian Panoramic Monochromator) without polarization analysis.

MTR gives high-resolution spectra simultaneously in several spectral lines and sequentially in the four Stokes parameters. MSDP gives high spectral resolution imaging simultaneously in several spectral intervals. IPM allows very narrow-band imaging scanning a line profile.

Thabit Ibn Qurra, Abu'l-Hasan (836–901)

Astronomer, born in Harran, Mesopotamia (now Turkey), became court astronomer in Baghdad, translated Greek works on mathematics and wrote on astronomy, including *Concerning the Motion of the Eighth Sphere*, on the apparent motions of the stars, analysed the movements of Sun and Moon and wrote treatises on sun-dials. Some of his books were translated into Latin by Gherard of Cremona and distributed in Europe.

Thales of Miletus (624–546 BC)

The first known Greek philosopher; also a scientist, mathematician and engineer, born in Miletus, Asia Minor (now Turkey), believed to have been the teacher of ANAXIMANDER. Apparently wrote a book on navigation, defining the constellation Ursa Minor and using it as a navigation aid. Credited with the prediction of an eclipse of the Sun in 585 BC, although it is not known how, since the Metonic cycle was known only for eclipses of the Moon at this time (eclipses of the Sun are harder to spot since solar eclipses are visible at different places on Earth, whereas lunar eclipses can be seen from half the Earth). Nevertheless the eclipse stopped the war between the Medes and the Lydians, according to Herodotus. Thales determined the height of pyramids by measuring the length of their shadow at the moment when a man's shadow is equal to his height. He taught that 'all things are water', which may seem an unpromising hypothesis, but was the first expression of the idea of explaining different phenomena from a common underlying cause, and foreshadowed scientific theory. Like the Egyptians, Thales believed that the Earth was a flat disc floating on an infinite ocean, explaining earthquakes as the shaking of the floating 'boat'. Thales was gazing at the sky one night and fell into a ditch, causing a servant girl to ask 'How do you expect to understand what is going on up in the sky if you do not even see what is at your feet' (the first absent-minded professor joke).

Tharsis Montes

The official name of the region on Mars known as the Tharsis Ridge or Tharsis Bulge, a large raised area in the northern hemisphere of Mars, centered at 2.8 °N, 113.3 °W. It takes its name from the ancient Spanish town known formerly as Tartessus. Tharsis is a large uplifted area, measuring 2105 km across at its greatest dimension, which contains the planet's most prominent volcanoes. In a 1000 km chain from northeast to southwest lie Ascraeus Mons (rising to 26 km above Mars's average surface level), Pavonis Mons (18 km) and Arsia Mons (20 km), all of which are 150 km or so across, while 1000 km to the northwest is the solar system's largest volcano, Olympus Mons. These peaks apart, the highest point on the Tharsis Bulge is the complex fractured terrain named Noctis Labyrinthus, with an elevation of 11 km. This is part of an extensive fracture system aligned approximately on the center of Tharsis; other prominent fractures are Ceraunius Fossae to the north and Claritas Fossae in the south. From the east of the Tharsis region, the giant canyon system of Valles Marineris extends eastward. It may be that the whole region was uplifted by an upwelling in the underlying mantle, possibly as a consequence of the event that created the impact basin Hellas on the opposite side of the planet.

The 2dF Galaxy Redshift Survey

The 2dF Galaxy Redshift Survey (2dFGRS) produced a three-dimensional map of the distribution of 221 000 galaxies covering 5% of the sky and reaching out more than 3 billion light-years to a redshift $z \approx 0.3$. The survey used the Anglo-Australian Telescope's (AAT's) 2-degree Field facility (2dF), which could observe 400 objects simultaneously over a 2° diameter field of view. Survey observations began in 1997 and were completed in 2002; the final survey was an order of magnitude larger than any previous redshift survey.

The 2dFGRS yielded the first map of the large-scale structure in the local (low-redshift) universe to probe a statistically representative volume on scales from tens of kiloparsecs to hundreds of megaparsecs. Analysis of the map gave the first direct evidence that the large-scale structure of the universe grew through gravitational instability, and provided a precise measurement of the mean mass density of the universe. The observed structure also displayed a weak signature produced by the interactions between baryons and photons in the very early universe, providing an estimate of the ratio of baryonic matter to dark matter. The combination of the 2dFGRS observations of the structure in the present-day universe with observations of the structure in the very early universe from the cosmic microwave background (CMB) gave precise measurements of the Hubble constant, and the cosmological constant and provided an improved upper limit for the mass of the neutrino.

The massive sample of galaxies observed by the 2dFGRS has also been used to precisely characterize multiparameter distributions and relationships within the galaxy population: the distribution of galaxies over luminosity, surface brightness, spectral type, star-formation rate and environment (local density) and the variation in clustering for galaxies of different luminosities and spectral types. The survey also yielded the first measurement of the galaxy bias parameter, which links the fluctuations in the number of galaxies and the amount of dark matter and is a basic constraint on models of galaxy formation and evolution.

The History of the 2dFGRS

The seed of the 2dFGRS was planted in the late 1980s, when a British astronomy review gave high priority to converting existing telescopes to wide-field science, especially multi-object spectroscopy. For the AAT, the case for such a conversion was greatly strengthened when Roderick Willstrop and Charles Wynne showed that, with suitable correction optics, the telescope could be adapted to permit a 2° diameter field of view at the prime focus (Willstrop 1987; Wynne 1989).

The Anglo-Australian Observatory, under Director Russell Cannon and instrumentation scientist Keith Taylor, combined this opportunity with its established strength in robotic multi-object spectroscopy in order to develop a wide-field, multi-object spectrograph: the 2dF facility (Taylor and Gray 1990; Gray *et al.* 1993). With massive field-correction optics including an atmospheric dispersion compensator, a pair of tumbling focal planes to minimize dead time, 400 optic fibers mounted in magnetic buttons, a fully robotic positioning system, and end-to-end software for control, configuration, data-taking and reductions, 2dF was, for its time, a visionary instrument. Construction began in 1990.

From its conception, the main scientific driver for 2dF was a massive redshift survey, sampling a representative volume of the universe in fine detail in order to precisely measure fundamental cosmological parameters. The best existing and ongoing surveys in the early 1990s (e.g. the IRAS Point Source Catalogue redshift survey and the Las Campanas Redshift Survey) either did not cover sufficiently large volumes to be statistically representative of the large-scale structure or covered large volumes too sparsely to provide precise measurements. An order-of-magnitude increase in the volume and sample size of redshift surveys was required to enter the regime of 'precision cosmology'. This idea was developed into a concrete proposal by the founding members of the survey team during 1993 and 1994. The first survey proposal was submitted to the telescope time committees and the AAT Board in 1994, and envisaged a survey of 250 000 galaxies over 2000 deg^2 to a magnitude limit of b_J=19.5. The survey was estimated to require 125 nights on the AAT and was projected to be completed by the end of 1996.

In fact, 2dF was placed on the AAT in November 1995, and the first spectra were taken in mid-1996. Scheduled observations with 2dF at full functionality began in September 1997, and the first major redshift survey observing run occurred in October 1997. Progress with the survey was slow to begin with, but the survey passed 50 000 redshifts in mid-1999 and 100 000 redshifts in mid-2000 (Colless 1999). The first 100 000 redshifts and spectra were released publicly in June 2001 (Colless *et al.* 2001), and the 200 000-redshift mark was achieved towards the end of 2001. The survey observations were completed in April 2002, after 5 years and 272 nights on the AAT.

The 2dF Wide-Field Fiber Spectrograph Facility

As its name implied, the 2dFGRS was tightly coupled to the capabilities of the 2dF of the AAT. The crucial parameters of 2dF for a massive redshift survey were as follows: (i) the wide (2° diameter) field of view, which allowed the 1800 deg^2 of the survey to be covered with 900 overlapping fields; (ii) the large number

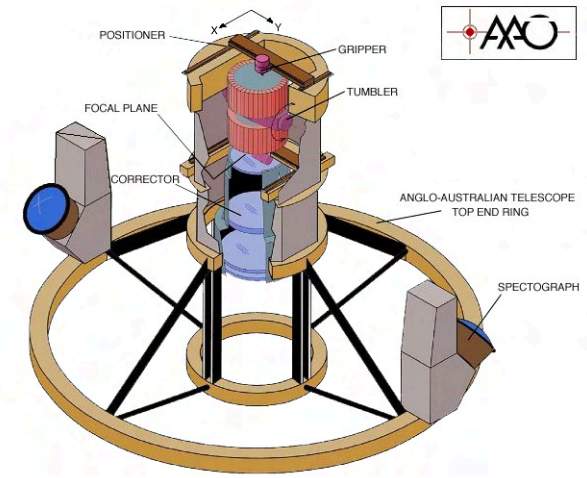

Figure 1. A schematic of the 2dF facility showing the major components of the instrument. (K. Taylor, Anglo-Australian Observatory.)

(400) of simultaneous spectra, which allowed the typical number of galaxies in the field of view down to b_J=19.5 to be observed at once; (iii) the 4 m aperture of the AAT, which allowed redshifts to be measured for galaxies as faint as b_J=19.5 in 1 h observations; (iv) the capacity for rapid reconfiguration, which meant that there was no dead-time between observations of different fields.

To achieve these complex requirements, a complex instrument was required. All the components of 2dF are contained in the 2dF top-end ring structure, which is mounted at the prime focus of the AAT (see figure 1).

A photon reflected by the AAT's 4 m primary mirror towards the prime focus encounters, first, the wide-field corrector optics (including an atmospheric dispersion corrector) that provide a 2° diameter field of view with good imaging properties; then it is collected at the focal plane by the fiber buttons that route it down the optic fibers; finally, it enters one of the twin spectrographs, each of which measures the spectra from 200 fibers at a time. The total system efficiency is about 5%.

The fiber buttons are magnetically attached to a metal plate in the focal plane. They are positioned on the plate by a high-precision robot, which moves over the plate on an X–Y stage and has a gripper arm that can be raised or lowered to pick or place a button on the plate. The robot can position a fiber button on the plate with a precision of 0.3 arcsec (20 μm) in 6 s. In order to maximize observing efficiency there are two sets of fiber buttons, and the plates

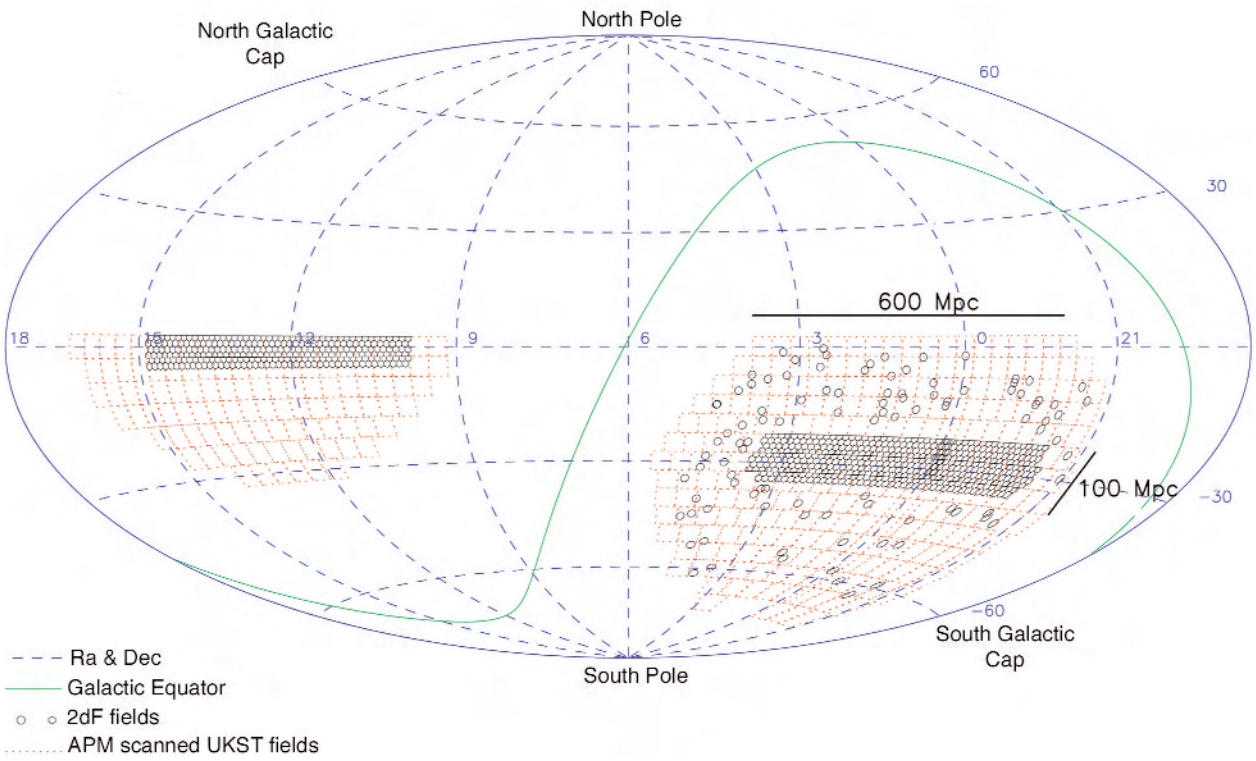

Figure 2. A map of the sky showing the locations of the two 2dFGRS survey strips (NGP strip at left, SGP strip at right) and the random fields. Each 2dF field in the survey is shown as a small blackcircle; the sky survey plates from which the source catalog was constructed are shown as small red squares. The scale of the strips at the typical redshift of the survey is indicated. (S. J. Maddox, University of Nottingham.)

on which they sit are tumbled between the focal plane position and the robot position. This allows the robot to configure the fibers on one plate while the fibers on the other plate are observing the sky.

A full technical description of the 2dF facility is given by Lewis *et al.* (2002).

Survey Observations

The source catalog for the 2dFGRS survey was a revised and extended version of the APM galaxy catalog (Maddox *et al.* 1990), which was created by scanning the photographic plates of the UK Schmidt Telescope Southern Sky Survey. The survey targets were chosen to be galaxies with extinction-corrected magnitudes brighter than b_J=19.5. The galaxies were distinguished from stars by an image classification algorithm that was conservatively designed to include all galaxies at the expense of also including a 5% contamination of the sample by stars.

The main survey regions were two declination strips, one in the southern Galactic hemisphere spanning 80° × 15° around the South Galactic Pole (the SGP strip), and the other in the northern Galactic hemisphere spanning 75° × 10° along the celestial equator (the NGP strip); in addition, there were 99 individual 2dF 'random' fields spread over the southern Galactic cap (see figure 2). The survey covers approximately 1800° and has a median redshift depth of z=0.11. An adaptive tiling algorithm was used to optimally place the 900 2dF fields over the survey regions, giving a highly complete and uniform sample of galaxies on the sky.

Redshifts were measured from 2dF spectra that covered the range from 3600 Å to 8000 Å at a resolution of 9.0 Å. Redshift measurements were obtained both from cross-correlation with template spectra and from fitting emissioning lines. All redshifts were visually checked and assigned a quality parameter Q in the range 1–5; accepted redshifts (Q>3) were found to be 98% reliable and to have a typical uncertainty of 85 km s^{-1}. The overall redshift completeness for accepted redshifts was 92%, although this varied with magnitude.

Figure 3 shows a thin slice through the three-dimensional map of over 221 000 galaxies produced by the 2dFGRS. The observer is at the center of the map, with redshift increasing towards the edge and angle on the sky (RA) marked around the circumference. This 3° thick slice passes through both the NGP strip (at left) and the SGP strip (at right). The decrease in the number of galaxies towards higher redshifts is an effect of the survey selection by magnitude—only intrinsically more luminous galaxies are brighter than the survey magnitude limit at higher redshifts. The clusters, filaments, sheets and voids making up the large-scale structures in the galaxy distribution are clearly resolved. Importantly, there are many such structures visible in the figure, demonstrating that the survey volume comprises a representative sample of the universe.

Cosmological Results

Although survey observations finished in April 2002, as of this writing the scientific analysis of the survey is still in progress. So far the main results to emerge have been cosmological, in keeping with the primary goals of the survey as it was envisaged a decade ago when 2dF was being built.

The first step in this analysis is a statistical characterization of the large-scale structure in the galaxy distribution, which in most cosmological models is fully described, at least on the largest scales, by just two quantities: the mean density and the variation in the typical size of the fluctuations in the density as a function of scale. The latter is best quantified on large scales by the power spectrum of the galaxy distribution, which Percival *et al.* (2001) measured from the 2dFGRS on scales up to 300 Mpc. The shape of the power spectrum is consistent with a cold dark matter (CDM) model having a shape parameter $\Gamma = \Omega_M h = 0.20 \pm 0.03$, which, for a Hubble constant around 70 km s^{-1} Mpc^{-1} (i.e. $h \approx 0.7$), implies a mean mass density $\Omega_M \approx 0.3$. The power spectrum also showed the weak signature of acoustic oscillations produced by baryon-photon coupling in the early universe, allowing Percival *et al.* to also estimate the mass fraction in baryons, $\Omega_b / \Omega_M = 0.15 \pm 0.07$.

The galaxy distribution on intermediate scales provides another measure of the mass density, and also a test of the fundamental assumption that structures grow due to gravitational instability. Under this paradigm, small-scale structures are undergoing non-linear collapse, while on larger scales structures are collapsing coherently. These effects lead to a characteristic distortion of the galaxy distribution observed in redshift space, with the small, high-density clusters of galaxies stretched out

along the line of sight and the larger, moderate-density filaments and sheets compressed along the line of sight. The first unambiguous detection of these redshift-space distortions was obtained from the 2dFGRS by Peacock *et al.* (2001), confirming that present-day structures are due to the gravitational amplification of small initial density fluctuations. The amplitude of the distortion depends on the quantity $\beta = \Omega^{0.6}/b$, where b parametrizes the bias of the galaxies with respect to the overall mass distribution. By measuring the compression of the galaxy two-point correlation function along the line of sight, Peacock *et al.* obtained $\beta = 0.54 \pm 0.09$ for galaxies with luminosities similar to the Milky Way. If such galaxies are relatively unbiased tracers of the galaxy distribution (i.e. $b \approx 1$), this also implies $\Omega_M \approx 0.3$.

Stronger constraints on these and other fundamental cosmological parameters were obtained by combining the power spectrum of the present-day galaxy distribution from the 2dFGRS with the power spectrum of the mass distribution at very early times derived from observations of the anisotropies in the CMB. Such analyses have been carried out by Efstathiou *et al.* (2002) and Percival *et al.* (2002), and show that the universe has a flat or near-flat geometry ($\Omega_k = 0 \pm 0.05$), with a low total matter density ($\Omega_M = 0.31 \pm 0.06$) and a large positive cosmological constant ($\Omega_\Lambda = 0.69 \pm 0.06$, consistent with the independent estimates from observations of high-redshift supernovae). The physical densities of cold dark matter and baryons are $\omega_c = \Omega_c h^2 = 0.12 \pm 0.01$ and $\omega_b = \Omega_b h^2 = 0.022 \pm 0.002$; the latter agrees very well with the constraints from big bang nucleosynthesis. The joint 2dFGRS+CMB analysis also provided an estimate of the Hubble constant ($H_0 = 67 \pm 5$ km s^{-1} Mpc^{-1}) that is independent of, but in excellent accord with, the results from the Hubble Space Telescope Key Project. Elgaroy *et al.* (2002) showed that these combined constraints place a strong upper limit on the neutrino mass fraction, $\Omega_\nu/\Omega_M < 0.13$ (95% confidence), which translates to an upper limit on the total neutrino mass (summed over all species) of $m_\nu < 1.8$ eV.

Another first for the 2dFGRS was the measurement of the bias, b, between the galaxy distribution and the underlying matter distribution, defined as the square root of the ratio of the galaxy and matter power spectra. Lahav *et al.* (2002) measured this ratio using the 2dFGRS and CMB power spectra, and found that for galaxies with characteristic (L^*) luminosities the bias parameter is $b^* = 0.96 \pm 0.08$. An independent analysis by Verde *et al.* (2002), using only the 2dFGRS and based on the higher-order correlations of the galaxy distribution in the quasi-linear regime, obtained a very similar result: $b^* = 0.92 \pm 0.11$. The conclusion is that L^* galaxies are nearly unbiased tracers of the mass distribution. However, Norberg *et al.* (2001, 2002a) showed that the bias parameter does vary with luminosity and spectral type, ranging from b = 1.5 for bright, early-type galaxies to b = 0.8 for faint, late-type galaxies.

The measurement of cosmological parameters from the 2dFGRS has made a significant contribution to shaping the current consensus model for the fundamental properties of the universe that has emerged from a range of independent observations, including the measurements of the CMB anisotropies, the distances to high-redshift supernovae and big bang nucleosynthesis.

Properties of the Galaxy Population

Alongside these cosmological studies, the 2dFGRS has also yielded a wide range of results on the properties of the galaxy population and provided strong new constraints for models of galaxy formation and evolution. Highlights in this area to date include the following: (1) precise determinations of the optical and near-IR galaxy luminosity functions (Cole *et al.* 2001; Norberg *et al.* 2002b); (2) a detailed characterization of the variations in the luminosity function with spectral type (Folkes *et al.* 1999; Madgwick *et al.* 2002); (3) a determination of the bivariate distribution of galaxies over luminosity and surface brightness (Cross *et al.* 2001); (4) the first precise measurement of the dependence of galaxy clustering on both luminosity and spectral type (Norberg *et al.* 2002a); (5) a constraint on the space density of rich clusters of galaxies from the velocity dispersion distribution for identified clusters (De Propris *et al.* 2001); (6) separate radio luminosity functions for AGN and star-forming galaxies (Sadler *et al.* 2001; Magliocchetti *et al.* 2002); (7) constraints on the star-formation history of galaxies from the mean spectrum of galaxies in the local universe (Baldry *et al.* 2002); and (8) a measurement of the environmental dependence of star-formation rates of galaxies in clusters (Lewis *et al.* 2002).

These results are just a fraction of the information that can be extracted from the 2dFGRS on the properties of galaxies and their relation to the large-scale structure of the galaxy distribution. Many more results are still to emerge from analysis of the survey and from combining the 2dFGRS with other large surveys and with detailed follow-up observations.

Bibliography

The 2dF Galaxy Redshift Survey web pages (www.mso.anu.edu.au/2dFGRS) contain detailed information about the survey, a gallery of images, an access point for the survey database, and a list of all 2dFGRS publications. The most relevant publications, referenced in this article, are as follows:

The Colors of Stars

The colors of the stars are real but not apparent. They are not seen by the unaided eye because stars are both intrinsically faint and at the same time minute points of light, almost always observed by a more-or-less dark-adapted eye. However, the colors of the stars are an important and quantifiable observational property that is indicative of their surface temperature. This in turn is a function of a star's mass and its evolutionary status. These ideas are brought together in the well-known color magnitude diagram, a cornerstone of stellar astrophysics (figure 1).

While in general star colors are not obvious to the unaided eye, a few stars (such as Antares and Betelgeuse) appear distinctly yellow–orange. However, most of the stars that appear similarly bright to the eye, such as those that define the constellations, are in reality as blue as the daytime sky, although this is not mentioned in the long history of non-telescopic stargazing. This is because the eye is not good at distinguishing delicate shades of blue when light levels are low and when the object size is small. Even with a telescope, star colors are usually only noted by observers of double stars who sometimes comment on the contrasting colors of closely adjacent stars.

The range of color from pale blue to deep orange–yellow found among the stars is familiar to photographers as the concept of color temperature, most usually where filters are required to adjust (for example) tungsten lighting to a film designed for daylight use. More broadly they are known as blackbody colors and

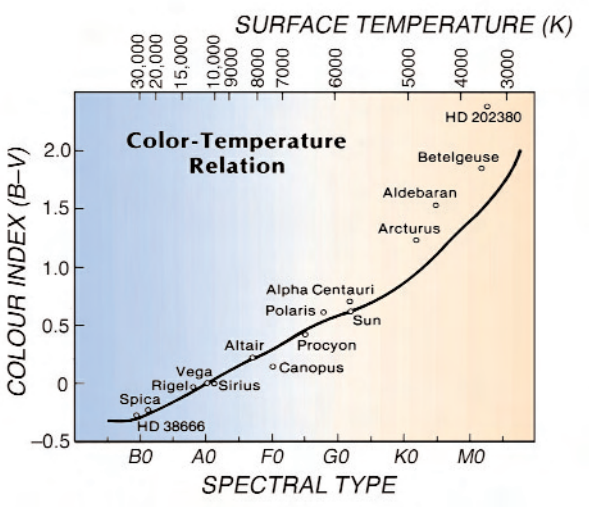

Figure 1. Most stars spend most of their lives on the main sequence, a narrow range of color and luminosity determined by the mass of the star. This diagram shows a few well-known stars dotted along the main sequence, plotted according to their surface temperature and *B*–V color index. The background color represents the color of the star

are the visible part of the radiation from any object that is at a temperature above about 1000 K (727 °C). The universe is full of such thermal radiation and much of it is invisible, originating from bodies much cooler than 1000 K. The ubiquitous microwave background radiation is a remnant of a time when the universe was unimaginably hot but now corresponds to a temperature of just 2.73 K above absolute zero.

The reality of star colors can be demonstrated in several ways. One of the simplest is to look at a bright star through a defocused telescope. This is normal practice when (for example) manually focusing a telescope using a Foucalt knife-edge, so that the star's light fills the field of view (the so-called Maxwellian view). Although I did this fairly regularly in preparation for photographic observing on the Anglo-Australian Telescope, my color memory (or maybe my color discrimination) was never good enough to distinguish reliably between randomly chosen O and B stars which are hot and bluish, but cooler F and G stars were easier to identify and differences between the yet cooler K and M stars were obvious.

A more convincing demonstration of the reality of star colors is a simple photographic experiment that involves making a star-trail photograph. From a dark site and beneath a clear night sky, a time exposure made with a camera loaded with color film captures the long, narrow trails of the stars, moved across the film by the rotation of the Earth. However, if the lens is regularly defocused in a series of steps every 5 min or so during the exposure, the stepwise spreading of the star images on the film effectively changes the exposure of each star image on the film. At some stage the colors of all the stars in the field are revealed. The example included here (figure 2) is the constellation of Orion, photographed on daylight slide film.

The realization that some stars were much bluer than others came in the 1890s when the relative magnitudes of stars in the early photographic catalogues were compared with stellar magnitudes obtained visually. It was gradually appreciated that the eye and the early photographic plates saw things differently. The plates of the time were sensitive only to blue and ultraviolet light, while the eye's maximum sensitivity was in the yellow–green part of the spectrum. This difference between the blue (*B*) photographic magnitudes and the visual (*V*) magnitudes was eventually understood as a way of measuring the colors of stars, and is the origin of the still widely used *B*–*V* color index.

Of course, the eye is no longer used for stellar photometry, so this deceptively simple system uses optical filters with well-defined characteristics to make two measurements in two well-separated color bands, nowadays using an electronic detector. Only after two-color systems were established was it realized that the difference in energy in the two passbands amounted to

Figure 2. Step focus image of the colors of the stars in Orion, made on daylight color film by defocusing the camera lens in a series of steps during a normal star trail exposure.

measures of the slope of the blackbody radiation distribution. In the visible part of the spectrum this is seen as a color shift. Stars are not perfect blackbodies, but allowances can be made for this, and thus measuring temperatures using the colors of stars became fundamental to understanding and classifying them.

The zero point (i.e. white point) of the $B–V$ color index system currently used is defined as an A0 star, which happens to be the color index of Sirius, the brightest star in the sky. However, A0 stars have surface temperatures of 10 000 K, a temperature that we would see as quite blue if the star was as big as the Sun in the sky. Regrettably, this does not stop astronomers describing stars such as Sirius as white and stars cooler than Sirius as yellow, or even red. If there are some truly red stars they are intrinsically extremely faint. The famous bright, so-called red giant stars such as Betelgeuse and Antares are actually several hundred kelvins hotter (and therefore bluer) than most domestic tungsten filament lamps. Although light from these lamps undoubtedly has a 'warm' color, not even an astronomer would describe it as red.

The Cosmological Constant and its Interpretation

The cosmological constant was first introduced into the equations of general relativity by Einstein himself, who later famously criticized this move as his 'greatest blunder'. His main motivation had been to allow cosmological models featuring a static universe, but this possibility swiftly became redundant with Edwin Hubble's discovery of the expansion of the universe. Despite this, it has periodically been invoked by astronomers to explain various phenomena and currently is a key part of the standard cosmological model, which seeks to explain both the evolution of large-scale universe and also the development of structures, such as galaxies, within it.

The most straightforward description of the cosmological constant is that it represents the energy of empty space. Usually physical laws only concern the *difference* in energy between two states (nature favouring evolution with force directed towards the state of lowest potential energy) rather than the absolute value of energy, but relativity demands that all energy gravitates and so the zero point of energy must be specified. The Einstein equation can be written

$$G_{\mu\nu} = g_{\mu\nu}\Lambda + 8\pi G T_{\mu\nu}$$

where $G_{\mu\nu}$ is the Einstein tensor measuring the curvature of space–time (which gives the gravitational attraction), $T_{\mu\nu}$ is the energy–momentum tensor measuring the properties of matter, $g_{\mu\nu}$ is the metric of space–time and Λ is the cosmological constant. Throughout the speed of light will be set to $c = 1$. If $\Lambda = 0$, then an absence of matter ($T_{\mu\nu} = 0$) leads to an absence of space–time curvature, but if Λ is non-zero we have gravity associated with the vacuum.

Although Einstein regretted the introduction of the cosmological constant, which certainly reduces the elegance of the equation, once it has been introduced it becomes rather hard to argue that it should not be there. There is no fundamental principle to exclude it, and indeed as we will see modern particle physics requires its consideration.

Cosmological models

Cosmological models including a cosmological constant are described in detail under COSMOLOGY: STANDARD MODEL. The Friedmann equation describes the evolution of the scale factor of the universe, $R(t)$, according to

$$\left(\frac{\dot{R}}{R}\right)^2 = \frac{8\pi G}{3}\rho + \frac{\Lambda}{3} - \frac{k}{R^2},$$

where ρ is the density of matter, k measures the spatial curvature and the dot indicates time derivative. If preferred, the cosmological constant can be included as a form of matter by defining $\rho_\Lambda = \Lambda/8\pi G$. The effect of the cosmological constant can be seen more clearly from the acceleration equation,

$$\frac{\ddot{R}}{R} = \frac{4\pi G}{3}(\rho + 3p) + \frac{\Lambda}{3}$$

where p is the pressure. While the density ρ always decelerates the expansion, a positive cosmological constant favors acceleration and hence acts as a repulsion. Indeed, in the limit where the cosmological constant dominates, the solution is an exponential expansion

$$R(t) \propto \exp\left(\sqrt{\Lambda/3}\,t\right).$$

Studying the way in which Λ enters these equations indicates that it can be considered as a fluid with equation of state $p_\Lambda = -\rho_\Lambda$.

There is a characteristic scale for the density, known as the 'critical density', which gives rise to a spatially-flat universe, $k = 0$. On defining the Hubble parameter, which measures the expansion rate, as $H \equiv \dot{R}/R$, the critical density is

$$\rho_c = \frac{3H^2}{8\pi G}.$$

It is often useful to consider the densities of the different components as fractions of this, by defining the density parameter $\Omega = \rho/\rho_c$ and the cosmological constant density parameter as

$$\Omega_\Lambda \equiv \frac{\rho_\Lambda}{\rho_c} = \frac{\Lambda}{3H^2}.$$

The condition for a flat universe is therefore that the sum of the Ω over all types of material is equal to unity.

In general the cosmological constant adds considerably to the possible phenomenology of big bang models. For example, there are models where the cosmic repulsion is so strong that there is no big bang, with the universe instead contracting and then bouncing. There can be open universe models which recollapse and closed universe models which expand forever; it is even possible to construct closed universe models where an observer can (if they wait long enough) see right round the universe. Another possibility is a long 'loitering' phase where the universe stays almost constant in size for a protracted period. However, the main focus has been on models which expand from an initial singularity and where the cosmological constant is negligible at early stages, only beginning to manifest itself at recent cosmological epochs.

Observational evidence for Λ

Observations in recent years have established a standard cosmological model where the present density of the universe is dominated by a cosmological constant. It is fair to say that cosmologists have been reluctant to include the cosmological constant but have been forced into it by the quality of a variety of observations, which paint a consistent picture depending on its presence. The main supporting evidence falls into two classes. One is

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

direct probing of the expansion rate of the universe by measuring the properties of distant objects, in this case supernovae. The second is to determine the density of matter in the universe and compare with the total density as inferred from the geometry of the universe.

Distant supernovae of type I, believed to be fueled by the collapse of an accreting white dwarf to a neutron star, are an excellent probe of the expansion rate of the universe because their absolute brightness is believed to be nearly the same for each explosion, with empirical corrections available to improve the uniformity of the sample even more. This means that they can be used to study the dependence of the luminosity distance (see COSMOLOGY: STANDARD MODEL) on redshift. This relation is known as the HUBBLE DIAGRAM, with supernovae now able to map this out to redshifts approaching unity. This relationship can be related to the expansion history of the universe $R(t)$, which the Friedmann equation shows is sensitive to the presence of a cosmological constant. Constraints on the densities of the cosmological constant and of matter are shown in figure 1 as the full and broken contours, and almost all the preferred region has a positive cosmological constant (and indeed a currently accelerating universe).

The second observational route concerns the matter budget of the universe. Recent cosmic microwave background anisotropy measurements have given strong evidence that the universe is spatially flat, or at least very nearly so (also shown in figure 1 as the dark shaded region). This requires that the total density of the universe, including the cosmological constant, must add to the critical density. However, there is plentiful evidence that the density of matter is well below this. For example, studies of clusters of galaxies show that there is about eight times as much dark matter as protons and neutrons, the latter being constrained by the formation of light elements to be about 4% of the critical density. Alternatively, the observed clustering properties of galaxies are known to be reproduced only if the dark matter density is around 30% of critical. Finally, direct estimates of the amount of matter providing gravitational attraction always fall well below the critical density. There is therefore a substantial shortfall in reaching the critical density required by the cosmic microwave background observations, a gap which must be filled by a form of material which does not clump gravitationally. The cosmological constant fits the bill perfectly.

Accordingly, the currently favoured cosmological model features a cosmological constant at around two-thirds the critical density, with matter making up the remaining third. The latter is mostly dark matter, but includes also the conventional matter from which we are made as well as the cosmic radiation backgrounds.

In summary, current observations strongly favor cosmological models with a flat spatial geometry ($k = 0$)

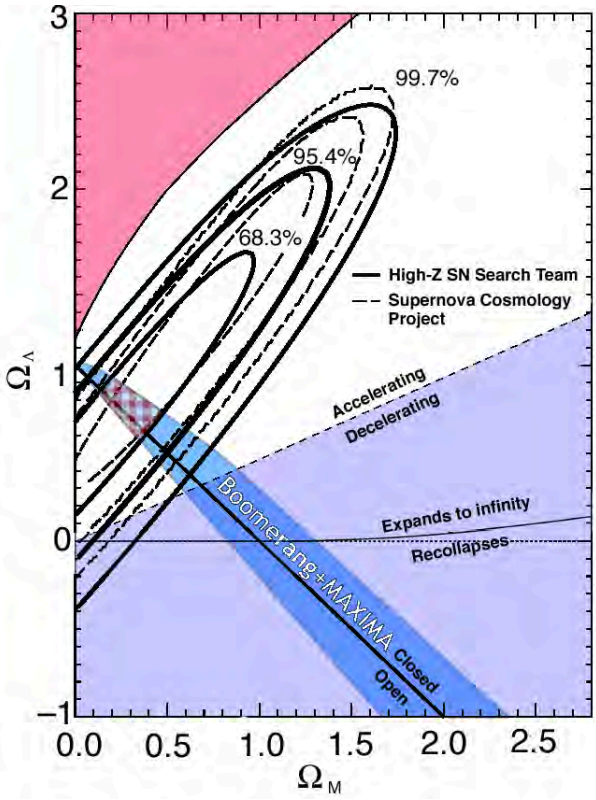

Figure 1. Constraints on cosmology from supernovae and the microwave background. The horizontal axis is the density of matter (including dark matter) as a fraction of the critical density, while the vertical axis is the density of the dark energy. The contour lines show the favored region from two separate studies of distant supernovae. The shaded diagonal band shows the region allowed by measurements of the anisotropies of the cosmic microwave background by the Boomerang and Maxima experiments. In combination, these allow only the small checked region, where the cosmological constant density is about twice that of the matter. (Figure courtesy Brian Schmidt; see also http: / / cfa-www.harvard.edu / cfa / oir / Research / supernova / HighZ.html.)

and which are accelerating at present. The simplest interpretation of the observed acceleration is that the universe possesses a cosmological constant.

The cosmological constant in particle physics

Explaining the observed magnitude of the cosmological constant is regarded as one of the outstanding problems in particle physics. This is because particle physics theory indicates that the magnitude of the cosmological constant should be huge, vastly greater than is observed. The reason is that in quantum physics one expects a zero-point energy to be associated with every kind of particle, and therefore that there should be an energy density associated with the vacuum.

It is not hard to see that the vacuum energy density is equivalent to a cosmological constant. If all observers

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

are to agree that a given state is the vacuum, then its energy–momentum tensor must be Lorentz invariant. The only tensor with this property is a multiple of the metric tensor $g_{\mu\nu}$ and hence we can write

$$T_{\mu\nu}^{\text{vacuum}} = -\frac{\Lambda}{8\pi G} g_{\mu\nu},$$

which ensures that the vacuum energy density does act precisely as a cosmological constant.

To assess the magnitude of the problem, we should first convert the observed value of the cosmological constant into particle physics units. Its equivalent mass density $\rho_\Lambda = \Lambda/8\pi G$ can be taken to be about two-thirds the critical density, giving

$$\rho_\Lambda \simeq 6 \times 10^{-27}\ \text{kg m}^{-3} \Rightarrow \rho_\Lambda \simeq (0.002\text{eV})^4.$$

This energy scale, written in electronvolts, is tiny compared with known characteristic energy scales of particle physics (for example the proton mass–energy is around 10^9 eV).

In quantum mechanics, unlike in classical physics, the vacuum state is a seething state where particles are constantly coming in and out of existence. There is a zero-point energy (the analog of the residual energy left in a gas at a temperature of absolute zero) associated with each possible particle state, which can be added up to give an estimate of the zero-point energy. Unfortunately the most simplistic calculations give an infinite answer, as each momentum state gives an equal contribution and there are an infinity of them; this indicates that the theory used to compute the contributions cannot be valid to infinite energies.

However, to what energies should the calculation be believed? According to present understanding, we are limited by the Planck energy, at which point gravity would have to be described by a quantum theory. The cosmological constant should therefore be approximately equal to the Planck energy density. Unfortunately, this is a massive $(10^{28}\ \text{eV})^4$, larger than the observed value of the cosmological constant by a factor of around 10^{120} (earning this calculation the description as 'the worst order-of-magnitude estimate in history'). This situation can be improved a little by conceding that actually we do not really understand physical laws above the energy scales probed by large particle accelerators such as CERN, and indeed a popular theory known as supersymmetry predicts that at higher energies a new theory comes into play that would ensure no contributions to the cosmological constant from energies much above those currently probed. Particle accelerators operate up to energies of around 10^{12} eV, so plausibly we can reduce our estimate to $(10^{12}\ \text{eV})^4$, reducing the embarrassment to a mere factor of 10^{60}!

It is currently believed that superstring theory (or its more elaborate cousin M-theory) is a strong candidate as a theory of quantum gravity. In principle it should therefore make much more definite predictions for the cosmological constant, as it is not subject to the cut-offs described above. However, current incarnations of superstring theory have not been developed sufficiently to allow unambiguous predictions to be made at this stage.

The historical cosmological constant problem was to explain why the cosmological constant appeared to be zero, despite the prediction that it should be huge, and investigations focused on various cancellation mechanisms and symmetry principles which might justify why the precise value of zero might be favored. However, the astronomical observations just described have, if anything, made the problem worse, as they demand an explanation for why the cosmological constant is both tiny *and* non-zero. No compelling, or even just plausible, explanation has yet arisen.

Dark energy/quintessence

While a cosmological constant can indeed give the observed accelerated expansion of the universe, it is not the only explanation. Since the early 1980s, it has been popular to suppose that the universe underwent a period of acceleration during its extremely early stages, known as INFLATION. Such a period of inflation cannot continue forever, because that would spoil the outstanding successes of the hot big bang model, such as nucleosynthesis and the origin of the cosmic microwave background. Early universe inflation therefore cannot be driven by a pure cosmological constant, but rather must be caused by a transient phenomenon mimicking a cosmological constant.

Much effort has gone into modeling inflationary expansion, and the standard mechanism is to assume that the universe is temporarily dominated by the potential energy of a scalar field. A scalar field describes a collection of spin-zero particles (which are popularly used in particle physics models to describe the breaking of symmetries), with the potential energy measuring the combination of the mass density of the particles and their binding energy. Under the right circumstances, such a scalar field can drive a temporary period of accelerated expansion, which comes to an end with the scalar particles decaying into conventional matter (see INFLATION for full details).

These ideas are an equally valid mechanism for driving acceleration in the present universe and provide an alternative to a pure cosmological constant that many cosmologists find attractive. The term 'dark energy' is now widely used to indicate any method of driving accelerated expansion, encompassing both the pure cosmological constant and any other method of obtaining an acceleration. This phrase is on no account to be confused with dark matter (see DARK MATTER: ITS

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

NATURE), which has entirely different properties. The specific use of a scalar field to drive the acceleration is usually referred to as 'quintessence' (the other four 'essences' of the universe being the baryons, the photons, the neutrinos and the dark matter). In the case of quintessence, it is presumed that any pure cosmological constant must be identically zero, for some as-yet-undiscovered reason.

This more general setting allows the possibility that the density of the dark energy may not be strictly constant, as in the case of the cosmological constant. This can be quantified via the equation of state parameter w_Q, defined by

$$p_Q = w_Q \rho_Q$$

where the subscript Q indicates that we refer to the density and pressure of the dark energy component. A pure cosmological constant has $w_Q = -1$, whereas to drive an accelerated expansion requires only $w_{\rm tot} < -1/3$, where $w_{\rm tot}$ is the combined equation of state of the dark energy and the other matter components (including dark matter) weighted by their densities. With observations indicating roughly twice as much dark energy as other matter, accelerated expansion will result provided that w_Q is less than about –0.5.

The quintessence energy density appears in the Friedmann equation, which for a flat universe reads

$$\left[\frac{\dot{R}}{R}\right]^2 = \frac{8\pi G}{3}(\rho + \rho_Q),$$

where we will have

$$\rho_Q \propto R^{-3(1+w_Q)}.$$

If the density of dark energy is varying, the solution for the scale factor $R(t)$ will be different to that obtained with a pure cosmological constant, and this provides possible observational signatures. It modifies the relation between luminosity distance and redshift, as probed by distant supernovae, and instead of using those data to constraint the densities of a cosmological constant and conventional matter, one can assume a flat universe and attempt to simultaneously constrain the density of dark energy and its equation of state. Another effect is that the altered expansion rate will change the growth rate of density perturbations in the dark matter, modifying the structure formation process. Finally, the angular diameter distance to the last scattering of the cosmic microwave background will be modified, leading to a shift in the angular size of features (the positions of the acoustic peaks).

Several studies of these effects have been made, and as yet no evidence has been found for variation in the density of dark energy. The pure cosmological constant remains a viable explanation of the observational data, and observations require that the equation of state w_Q be less than about –0.7 (at 95% confidence). Upcoming observations, perhaps including a satellite-based supernova search, have the capacity to significantly strengthen this constraint and hence may detect a time variation of the dark energy if it is sufficiently large.

If the dark energy is permitted to have time variation, it must also be able to support spatial variations, in the form of density perturbations. In principle these can interact with and affect perturbations in the dark matter, modifying the process of structure formation which may lead to further observational tests. However in practice these effects are highly suppressed in realistic models and it is likely to be very hard to determine the properties of dark energy through studying these effects.

If we appeal to the same physical mechanism both to drive the inflationary acceleration of the early universe and the present-day acceleration, does that mean that the same scalar field might be responsible for both? In most models the answer is no, because of the vastly different energy scales involved; we are using the same physical mechanism, but the two fields are not connected. However, it is possible to contrive models where the same field is responsible; Peebles and Vilenkin called such models 'quintessential inflation'. As the same scalar field has multiple duties to attend to, it has many more observational requirements that it must satisfy and so such scenarios can be quite strongly constrained. However, fundamental particle physics indicates we should expect many scalar fields to exist in nature, so there seems little motivation to force one of them into doing all the cosmological work. Accordingly, most attention has been directed at models where early universe inflation and the present dark energy are separate phenomena.

The cosmological constant coincidence

In addition to the daunting task of understanding the numerical value of the cosmological constant, it poses a further problem known as the 'coincidence problem'. It is an apparent coincidence that we are developing our understanding of cosmology during the fairly brief epoch (brief by cosmological standards—a few billions of years in actuality) where the cosmological constant has a density similar to that of other matter. The ratio of densities of the cosmological constant to dark matter goes as the cube of the scale factor; when the universe was a tenth its present size the cosmological constant was utterly negligible, while once the universe has doubled its present age it will be completely dominant.

One of the advantages of the dark energy hypothesis is that, in enabling the density of the effective cosmological constant to vary, it may open routes to explaining this coincidence. Unfortunately, however, no compelling model has yet arisen, despite considerable interest in so-called 'tracker models' where a quintessence field responds to, and in some cases mimics, the behavior of conventional matter.

An alternative route is to invoke the ANTHROPIC PRINCIPLE, which states that we should expect to see cosmological parameters take on values which give the universe which, out of all possible universes, is most amenable to the development of life. This approach can in principle explain both the numerical value and the coincidence, as a very large value of the cosmological constant will prevent galaxies from forming, while there is some indication that a significant value may enhance the number of galaxies produced. In this approach, we require fundamental physics to allow a wide range of possible values of the cosmological constant (which may be realized in widely separated regions of the universe, or even perhaps just in possible quantum states of the universe), and the precise value which arises in our part of the universe has no fundamental significance.

The Hobby–Eberly Telescope

The Hobby–Eberly Telescope (HET) has an 11 m diameter spherical primary mirror. It is one of the world's largest optical telescopes. It is located at McDonald Observatory in West Texas and its partners include the University of Texas at Austin, Pennsylvania State University, Stanford University, the Ludwig Maximillians University in Munich and the Georg-August University in Göttingen. Observing time is divided among the partners in proportion to each partner's financial contribution.

Because of the spherical primary mirror, the telescope is equipped with a spherical aberration corrector which sees a 9.2 m diameter piece of the primary mirror. During an observation, in order to compensate for the rotation of the Earth, the primary mirror is held fixed while the spherical aberration corrector is moved across the focal surface of the sphere in order to follow the reflected image of the star. The primary mirror is tilted with its optical axis 35° from the zenith and is mounted on a turntable allowing it to be rotated 360° in azimuth. This novel design causes the gravity sag of the primary mirror to be constant but limits the telescope to observe objects which are crossing a circle, centered on the zenith, whose radius is 35°.

The HET is designed primarily to do astronomical spectroscopy. Its initial complement of instruments includes a low-resolution spectrograph at the top of the telescope into which the light is shone directly and a medium-resolution and high-resolution spectrograph in the basement, under the telescope, which are fed by optical fibres carrying the light from the top of the telescope down to the instruments. The telescope is queue scheduled which allows it to observe targets of opportunity, such as supernovae, and to make regular observations of variable objects. Queue scheduling also allows more efficient use of the telescope and it allows one to adapt the schedule to the sky conditions.

Visitors to the McDonald Observatory are welcome to visit the George T. Abell Visitors Gallery attached to the HET. Visitors are welcome seven days a week and a new visitor centre will open late in 2001.

The Telescope (to 1950)

The TELESCOPE was the single greatest technical innovation in the history of astronomy, transforming it from a naked-eye study of celestial motions into a physical science. It revealed to humans a far richer and more complex universe than ever imagined. Its history proceeded in stages: a technological discovery led to a series of improvements until an impasse was reached. Another discovery would entail a different line of development, resulting in larger, better instruments. Some of these stages overlapped. Astronomical discoveries came in waves, as each innovation extended observers' views. Three important needs have driven telescope makers and users: greater light-gathering power with attendant resolution; sharper, brighter images; sturdier mountings.

From the astronomer's viewpoint, the choice of instrument depended on the object of research or the area of research was driven by the telescopes available. During the 18th and 19th centuries, the concentration on stellar positions, binary stars and visual planetary observations encouraged the development of REFRACTORS. The increasing importance of photography in the last quarter of the 19th century stimulated new optical designs and better mountings and drive systems. The 20th-century demand for more light-gathering power for spectroscopy and photography spurred the development of large REFLECTORS.

The early telescope

Invented in the Netherlands in the first decade of the 17th century—there were several claimants—the telescope became an astronomical instrument in the hands of GALILEO GALILEI. He fabricated his first telescope, essentially a spyglass, in 1609. His observations of the Moon, Jupiter's satellite system, Venus and the Milky Way, announced in the *Sidereus Nuncius* the following year, ensured the instrument's rapid adoption by astronomers. Galileo thus inaugurated the development of the REFRACTING TELESCOPE, one that employs an objective lens to capture and focus light, and an eyepiece of one or more lenses to straighten the light into a beam and to magnify the image. The GALILEAN TELESCOPE or Dutch telescope combined a double-convex objective lens and a double-concave eyepiece to produce an upright image, a limited field of vision and low magnification. Such instruments, many fabricated by Galileo, spread quickly, with sunspot observations being made by mid-1610. Such a design, however, severely limited observational discoveries.

In 1611, KEPLER, in his *Dioptrice*, suggested an alternative arrangement for a refractor, employing two double-convex lenses, which would yield a wider field and greater magnification, but an inverted image. He produced none himself, but, by the late 1640s, Francesco Fontana was observing with a Keplerian telescope of his own manufacture. Kepler also described spherical aberration. Given a lens with a spherical surface, rays of light incident near the outer edge will focus closer to the lens, while those incident near the center will focus slightly farther out, the result being an image that is out of focus. He reasoned that a hyperboloidal surface would solve the problem, although no optician could have ground such a surface. A second major defect of a refracting telescope is CHROMATIC ABERRATION. As different wavelengths of light are refracted at slightly different angles, the observer sees an image with colored rings. The two defects compound, giving blurry, colored images.

The disadvantages of the Keplerian design could be overcome somewhat by producing objective lenses with less curvature, which had longer focal lengths. Alternatively, one could stop down the objective, so light passed only through the central portion of the lens. The earliest instruments of the Keplerian type, like the Galilean form, were wooden tubes with lenses fixed in the ends. JOHANNES HEVELIUS, a Danzig brewer, was the first systematic observer with long-focal-length refractors. With a 12 ft instrument, he produced a lunar atlas in 1647. During the next decade, Christiaan and Constantijn Huygens, in the Netherlands, produced even longer refractors, turning them on the Saturn system. This stimulated Hevelius to build larger instruments, culminating in a 150 ft telescope, with an open, wooden framework tube suspended by ropes and pulleys. Flexure and vibration made such instruments extremely difficult to manipulate. The Huygens' solution was to dispense with tubes altogether, creating 'aerial' telescopes—one of which was more than 200 ft long—by joining the objective lens to the eyepiece by a thread. Both forms were clumsy, yet a surprising number of discoveries came from their use. An important center was the Paris Observatory, where J D Cassini made planetary observations with both forms, employing long-focus lenses provided by the Roman optician Giuseppe Campani. While the optical quality of many lenses, particularly from Italian opticians in the late 17th century, was good, mountings were poor. Shorter instruments could be propped up on windowsills or wooden frameworks. Almost all telescopes were employed out of doors.

Despite its drawbacks, the Keplerian refractor could be adapted to telescopic measurement. A number of astronomers, beginning in the 1650s, experimented with micrometers, which allowed the angular distance between two objects in view to be measured. As Robert Hooke showed in the late 17th century, telescopes could be mounted upon a variety of hitherto naked-eye instruments such as the quadrant, greatly improving the accuracy of position determination.

The reflecting telescope

Two technological pathways were followed in an attempt to make telescopes more effective. One was the development of a different optical system, the REFLECTING TELESCOPE; the second was to find a solution to the chromatic aberration problem in refractors. Although the idea of reflecting telescopes or hybrids using both mirrors and lenses had been discussed since Galileo's time, the first description of a modern reflecting instrument was made

Copyright © Nature Publishing Group 2001

by James Gregory in 1663. His suggestion of combining a perforated parabolic primary with a concave ellipsoidal secondary to reflect the image back to an eyepiece was beyond the opticians' art. His contemporary, Isaac Newton, investigating chromatic aberration, correctly linked dispersion with the refractive properties of a transparent medium. Assuming it could not be overcome, he produced the first workable reflector in 1672. In the familiar Newtonian form, its small primary mirror of speculum metal, an alloy of copper and tin with some arsenic, had a spherical surface. A small, flat mirror, set at an angle of 45°, diverted the light reflected from the primary to an eyepiece mounted on the side of the tube. However, the NEWTONIAN TELESCOPE suffers from SPHERICAL ABERRATION. At the same time, Cassegrain in France proposed a system like Gregory's but employing a convex secondary (see CASSEGRAIN TELESCOPE, GREGORIAN TELESCOPE), although no examples seem to have been made at the time.

By the 1720s, JOHN HADLEY, the inventor of the octant, solved the spherical aberration problem by producing mirrors with a parabolic figure. Within 20 yr, London optician James Short could provide sufficiently good primaries to construct Gregorian reflectors as a commercial enterprise. It was Hadley who designed a workable altazimuth mounting for reflectors, followed by Short. The latter also produced some simple equatorial mountings for his brass-tube instruments. As a research instrument, however, the reflector came into its own with William Herschel's work.

Herschel, a self-taught astronomer and optician, began casting and polishing his own mirrors in the early 1770s (see HERSCHEL FAMILY). Over the next decade, he produced increasingly larger mirrors, building Newtonian instruments with a variety of mountings. By the mid-1780s, he undertook his important 'sweeps' to discover nebulae and undertook star gauging with a 20 ft telescope with an 18.8 in primary. For convenience and for brightness of image, he dispensed with the Newtonian flat, tilting the primary mirror so the focus reached the rim of the tube's upper end, where an eyepiece could be laid. The scaffold-work altazimuth mounting allowed the tube to be slewed 30° horizontally without moving the base; vertical motion was effected by ropes and pulleys. By 1789, Herschel erected by far the largest telescope ever built, the 40 ft telescope with a 48 in primary. Similar to the 20 ft, it was more massive and difficult to operate and never much used.

By the turn of the 19th century, British manufacturers supplied a variety of smaller reflectors—Gregorians, Newtonians and Cassegrainians—but none followed Herschel's lead in fabricating large instruments. By the 1830s, John Herschel was still using his father's 20 ft instrument to great advantage at the Cape of Good Hope (see HERSCHEL FAMILY). Stimulated by Herschel's example, William Parsons, THIRD EARL OF ROSSE, began experimenting with casting and polishing large specula in the 1840s. This was a difficult and risky undertaking. Rosse assembled, and trained, a team of technicians who assisted in producing a variety of specula, some compound, and building innovative polishing machines along with casting and annealing equipment. Like Herschel, Rosse's finest instrument was not his largest but a 36 in Newtonian built in 1840. It performed well despite its poor site. Striving further, and with many technical issues to resolve, Rosse soon constructed his 72 in 'Leviathan'. No larger reflector would go into service until 1918, but it was an almost useless instrument, despite its role in showing the spiral structure of several nebulae. Mounted as a transit instrument between two stone walls, with a very small lateral motion, it was useful only for lunar or planetary work, and then only rarely at full aperture given the miserable observing conditions of the Irish midlands. Further discoveries would rest with astronomers armed with more modest equipment.

Development of the modern refracting telescope

The second line of development to improve telescopes resulted from experiments to deal with chromatic aberration in refractors. In 1729, Chester Moor Hall found that, by combining a convex crown glass lens with a concave flint glass lens, he could produce an achromatic objective. He was no optician and not until the 1750s did John Dollond begin producing such lenses commercially. The Dollond firm and, later, Jesse Ramsden, manufactured a wide variety of instruments with achromats. Although a real improvement over anachromatic lenses, the poor quality of flint glass limited their value. Still, small, specialized instruments were readily available from reliable makers such as Troughton, Tulley and Simms in England, and from several continental European firms such as the Repsolds of Hanover.

Until the mid 19th century, refracting telescopes were strictly visual instruments, used either on their own or as part of specialized instruments such as sextants, octants, transits and meridian telescopes for navigation, celestial mapping and timekeeping. Tubes came in a variety of materials, mostly wood and metal, with brass becoming dominant until the late 19th century, when steel supplanted it.

The refractor was brought to near perfection during the 19th century through a combination of improved optical glass technology and accurate, sturdy equatorial mountings. Achromatic objective lenses were limited by the quality of flint glass. Swiss optician P L Guinand developed a method in 1805 that produced flint glass with almost no imperfections. During a business venture in Munich, he tutored the young JOSEPH FRAUNHOFER in his method. Fraunhofer's later experiments with spectra allowed him to calculate lens curvatures and combinations that provided superior (although not perfect) images. Fraunhofer's other key contribution was the prototype of the modern German equatorial mounting. For his 9.5 in Dorpat refractor (1824), a steel polar axis was mounted on a wooden frame; the declination axis, attached to the top of the polar axis, held the telescope tube on one side,

Dirac House, Temple Back, Bristol, BS1 6BE, UK

the declination circle on the other; the counterweight was bolted to a separate arm. The polar axis was turned by a weight-driven clock with a centrifugal friction governor. With this instrument, then the world's largest refractor, F G W Struve undertook his remarkable work on binary stars.

With the introduction of the uniform driving of the polar axis by means of weight-driven clockwork, guiding became limited to minor adjustments during observation. Without clock-driven equatorial mountings, the introduction of photography and spectrography in the second half of the century would have been impossible.

By 1839, Georg Merz, a former assistant of Fraunhofer's, commenced operations of Merz and Mahler, the major German telescope firm until the 1880s. With high-quality optical glass, Merz provided the 15 in Pulkova refractor in 1839. Like the Dorpat instrument, it was used by Struve's son Otto for binary star measurements. Merz also supplied the Americans with their first large refractors: the 11 in Cincinnati telescope in 1843 and the 15 in Harvard College Observatory telescope for W C Bond in 1847. German manufacturers maintained a leading position with the association of two Jena firms, instrument maker CARL ZEISS and optician Otto Schott, after 1884. Zeiss did not produce large refractors until the 20th century, with 24 and 26 in instruments for Germany, Serbia, Indonesia and Japan in the 1910s and 1920s.

British manufacturers in the early 19th century could only produce modest refractors, having no source of good optical glass except for Guinand, by then based in France. Chance Brothers of Birmingham purchased the method from Guinand's successor in 1837. They, and Guinand's son and grandson in France, produced most of the world's objective lens blanks during the rest of the century. Better-quality glass and improvements in grinding and polishing machines and techniques were factors in the production of superior lenses. Another was the knife-edge method of testing optical performance, announced by Foucault in 1858. One could measure the focal length and find surface curvature imperfections of both lenses and mirrors. In the early 20th century, the procedure was supplemented by Hartmann's photographic testing method.

Although Americans had to obtain telescopes in Europe before 1850, their own opticians and mechanics quickly became world leaders in refractor technology. Henry Fitz produced many medium-sized refractors of excellent quality—his largest was 16 in—before the Civil War. In the late 1850s, ALVAN CLARK, who had no training in optical work, began figuring achromats. Using a method developed independently of Foucault's, Clark was able to find surface imperfections. Careful figuring, rather than calculating curvature, enabled him to produce superb lenses. His 18.5 in objective, intended for the University of Mississippi, was completed in 1862. Testing the lens, Clark's son, Alvan Graham Clark, discovered Sirius B. Because of the war, the telescope ended up in the old University of Chicago and, later, at Northwestern University. The Clarks soon produced 26 in refractors for the US Naval Observatory and the University of Virginia. More instruments were to follow, each in turn the world's largest: the Pulkova 30 in in 1883, the 36 in for the Lick Observatory in 1887 and the 40 in for the Yerkes Observatory in 1897. The objectives for last two were the work of A G Clark and C A R Lundin. With the completion of the Yerkes instrument, no larger refractor was ever constructed.

The Clarks, when building the Lick instrument, contracted the tube and mounting to a Cleveland machine-tool manufacturing firm, Warner and Swasey, which had only limited experience in the field. With that success, they repeated their partnership for the Yerkes' 40 in telescope. Warner and Swasey worked with both the Clark and the Pittsburgh firm of John Brashear on further refractor projects before turning to large reflectors.

European telescope makers were not idle during the second half of the century. Thomas Cooke was the leading English manufacturer of refractors by mid-century and the only one to produce a large one, the 25 in instrument for R S Newall, completed in 1871. In France, Paul and Prosper Henry, working with P Gautier, built several French refractors. In Germany, the Steinheil firm collaborated with the Repsolds on several projects. The Dublin instrument maker, Howard Grubb, produced several 15 in telescopes in the 1870s before producing his trademark instrument, the 27 in Vienna University refractor 1881, which featured a German equatorial mounting that became the model for all subsequent instruments. Grubb's works produced another half-dozen large instruments into the 1920s when the firm, purchased by Sir Charles Parsons (becoming Grubb-Parsons) moved to manufacturing reflectors.

Until the 1860s, astronomical photography, born in 1840, was practiced with visual refractors, which were not corrected for the violet end of the spectrum, to which photographic plates of the time were most sensitive. American amateur L M Rutherfurd produced special objectives for photographic work in the 1860s. By the 1890s, several firms—Grubb, T Cooke and Sons, Brashear and Clark—produced a number of different astrographic lenses for specialized instruments. If both visual and photographic work were wanted, two telescopes could be piggy-backed on one mounting. Alternatively, corrector lenses could be introduced to visual refractors for photographic work, a method with several drawbacks.

Other specialized refractors aided positional astronomy. In the late 17th century, Ole Rømer devised the first transit instrument, mounted on a horizontal axis so it moved only in the meridian. A partially circular scale, with a micrometer for more accurate readings, allowed the star's declination to be determined. With the better clocks by then available, star passages could be timed to determine their right ascensions. He also built the first meridian circle, which performed both tasks, but had a full-circle scale and could reach the entire visible meridian. These and variants became features of many observatories over the next two centuries. During the 19th century, British

Dirac House, Temple Back, Bristol, BS1 6BE, UK

manufacturers such as Troughton and Simms and Thomas Cooke produced portable transit instruments that could be taken into the field, which, with the use of the electric telegraph, allowed longitudes to be determined far from observatories.

We need to note also the evolution of an indispensable part of a telescope, the EYEPIECE. The basic Galilean telescope combined a single objective lens with a single biconcave, or negative, eyepiece lens. The Keplerian form also employed a single eyepiece lens—in this case a biconvex or positive lens. Both magnified the image and collimated the rays of light received by the eyepiece from the objective. As magnification is the ratio of the focal lengths of the objective and eyepiece, long-focal-length objective lenses could be paired with short-focal-length eyepieces for much higher magnifications in the Keplerian form. Single-lens eyepieces continued to be used for more than two centuries—William Herschel preferred them—but compound eyepieces appeared in the 1640s in Italy. HUYGENS developed the first standard compound system, comprising two planoconvex lenses (a field lens and an eye lens) with both curved surfaces facing the objective. A Huygens eyepiece offered a wider field of view. During the 18th century, Jesse Ramsden devised a variant using two planoconvex lenses of equal focal length in which the curved sides faced each other.

Two other general-purpose systems appeared by the mid 19th century. The Kellner or orthoscopic eyepiece combined a compound achromatic eye lens with a convex field lens to provide a wide field and nearly constant magnification over the field. The Steinheil and Zeiss firms produced a number of Kellner-type eyepieces. Another way to increase magnification was to introduce a concave lens in front of the eyepiece, an idea developed by Barlow in England. Such eyepieces, in a wide variety of magnifications and fields of view, were available to astronomers by the later 19th century. In practice, a high-powered eyepiece was useful only for lunar or planetary work, and then only under the best atmospheric conditions and with the sturdiest mounting.

The modern reflecting telescope

The later 19th century was the heyday of the large equatorial refractor, but the design and construction of the reflector was undergoing a quiet revolution. Lord Rosse's Leviathan was a dead-end, given its poor site, easily tarnished mirror and inflexible mounting. The last two examples of large speculum reflectors were WILLIAM LASSELL's 48 in Malta instrument (1860) and THOMAS GRUBB's 48 in Melbourne reflector (1869). Lord Rosse had followed Grubb's lead in supporting his mirrors, and Lassell emulated Rosse's methods for grinding and polishing, but, with the failure of the Melbourne instrument, the history of speculum reflectors ended.

A key breakthrough was the introduction of silvered glass primary mirrors by Foucault and others in the 1850s. When such a mirror tarnished, it need only be re-silvered, as opposed to the time-consuming and potentially ruinous refiguring required for speculum mirrors. HENRY DRAPER, a pioneer of astronomical photography, introduced the idea to America. English optician ANDREW COMMON produced a number of medium-sized crown glass mirrors, which found homes in several private and public observatories. His 36 in equatorial reflector, later donated by E Crossley to the Lick Observatory, showed the value of such instruments for photography. After C D Perrine built a new mounting early in the 20th century, the telescope became an outstanding research tool. By the late 1880s, Common showed that 60 in glass mirrors, both solid and with a hole in the center, could be made.

Common produced a number of primaries for observatories but was soon joined by competitors: the Henry Brothers in France, Brashear and the Clarks in the USA, Schaer in Switzerland and Zeiss in Germany. Some firms produced both the optical and mechanical parts for reflectors. An effective reflecting telescope required two other important features: a solid EQUATORIAL MOUNTING and a means to support the great weight of large mirrors. While refractors typically had German equatorial mountings, the reflectors from the mid 19th century featured a variety of arrangements. The cross-axis form, originated by Sisson in the 18th century, was exemplified by Grubb's Melbourne telescope and French telescope mountings designed by Gautier. Common used a fork mounting for his 60 in instrument, and others tried the English yoke mounting, improved by Ramsden.

Solving the flexure problem of large mirrors took more time. Lord Rosse, Grubb and Common had used counterweights on the back of the mirror to compensate for any sag when the mirror moved vertically. The standard solution for 20th-century instruments was G W RITCHEY's method used for the 60 in Mount Wilson reflector. The mirror was housed in a massive, cast-iron cell, with three adjustable pads for mirror collimation, a set of counterweighted pads attached to the back for flexure and a ring with counterweights to handle lateral movements.

Another factor in improved astronomical work was the realization that a large telescope necessitated an excellent site for the best seeing. Lassell, who worked in Malta, was the first to demonstrate this. Even in the 20th century, many of the major, especially national, observatories such as those in Greenwich, Paris, Pulkova, Washington or Ottawa had light-polluted, smoky and climatologically poor locations. Beginning with the Lick Observatory, astronomers began seeking the best possible sites when they could manage to do so economically or politically. Although George Ellery Hale had chosen a mediocre Wisconsin site for the Yerkes Observatory, he recognized the value of a good site and quickly developed Mount Wilson in California.

Although glass-on-silver reflectors of a modest size (<1 m) proliferated towards the end of the 19th century, it was Ritchey's fork-mounted 60 in telescope at Mount Wilson that demonstrated in 1908 that a powerful, accurate instrument for astronomical photography and spectrography could be built. Common had produced

equally large mirrors earlier but did not solve the mounting problem to build practical instruments. As a major focus of astronomical work after the turn of the century was stellar spectroscopy, the Cassegrain arrangement was considered most convenient to have ready access to the spectrograph. One could either cut out the hole in a primary or pour the molten glass into a mold with a core. Ritchey did not believe optical firms could produce blanks with holes without serious flaws and followed JAMES NASMYTH's method of introducing a third mirror just in front of the primary to deflect the light beam to the side of the tube. J S PLASKETT, in planning the 72 in reflector for Victoria, suggested that the St-Gobain works should force a core through the molten glass and a mirror with few imperfections resulted. Almost all subsequent large reflectors had holes cast in them.

Stimulated by Ritchey's example, Plaskett designed what became the standard model for large reflectors to the 1960s. He chose the cross-axis arrangement for ease of use and adopted Ritchey's method for mirror mounting and support. Because spectroscopy was the most important use for such an instrument, it had $f/5$ primary and $f/18$ Cassegrainian focal ratios. The 72 in primary of plate glass, provided by St-Gobain, was ground and polished by Brashear. Mechanical parts were supplied by Warner and Swasey. The telescope featured self-aligning ball bearings in the polar axis, electrical control and a quick-change method for substituting prime focus, Newtonian and Cassegrain arrangements in the upper tube.

Before 1950, three firms produced large reflectors, all using features based on the Dominion Astrophysical Observatory instrument. Warner and Swasey build a 69 in instrument for the Perkins Observatory, a 60 in for the Cordoba Observatory and its largest telescope, the 82 in McDonald Observatory telescope. The last, at Otto Struve's insistence, included a coudé arrangement for spectroscopy. For all Warner and Swasey telescopes, engineering design was provided by E P Burrell, later involved with the 200 in telescope project. J W Fecker, who once worked for Warner and Swasey when the Canadian telescope was being built, later provided two 60 in telescopes for Harvard, while completing the optics for the Cordoba instrument. The third firm was Grubb-Parsons, successors to Sir Howard Grubb. Its first large reflector was the 74 in telescope for Toronto's David Dunlap Observatory in 1935. It too was modelled on Plaskett's instrument. With only slight engineering changes—such as the provision for coudé work—Grubb-Parsons produced almost identical telescopes for Pretoria, Helwan and Canberra.

The large reflectors were the workhorses of astrophysical research during the first half of the century, most of their time being devoted to spectroscopy. A second evolutionary line of very large reflectors developed slowly from the pioneering work of Ritchey. While the 60 in telescope was under construction, G E HALE wished to secure an even larger mirror, in the event a 100 in blank of poor quality from St-Gobain. Ritchey worked on the mirror for several years, while he and his colleagues designed a massive yoke mounting. It went into regular service at Mount Wilson in 1918 and, for 30 yr, was the world's largest telescope. In the hands of Edwin Hubble and others, it became the front-line instrument for extragalactic studies. Its mounting was not emulated by manufacturers of conventional large reflectors.

Hale soon desired an even larger telescope and with his customary enthusiasm persuaded the Rockefeller Foundation to fund a 200 in reflector in 1928. It was clear that one could not merely scale up the 100 in instrument and new engineering and material problems required solution. The crown glass mirror, as used at Mount Wilson and Victoria, had too high a coefficient of expansion to be useful for such a large instrument. The US Bureau of Standards had been able to provide a superior borosilicate glass primary for the Perkins telescope. A commercial borosilicate glass emerged in Pyrex, manufactured by Corning Glass Works. In the early 1930s, while Corning experimented to see whether Pyrex would be suitable for Hale's new venture, a test blank for the 74 in Toronto telescope was cast. Proving successful in that instrument, Pyrex became standard for most large reflectors.

The weight of a 200 in disk would be enormous and a unique method of casting it with a ribbed back resulted. A more sophisticated method than Ritchey's was needed for mirror support. Neither a cross-axis nor a yoke arrangement for the mounting was suitable; a modified yoke, with an open horseshoe-shaped upper end of the polar axis provided support, stability and access to all parts of the sky. A triumph of pre-war engineering, the massive telescope could be moved with ease by small electric motors. Because of wartime delays, the 200 in telescope did not see first light until 1948. It would remain the world's largest until 1975.

Most conventional reflectors had primaries of $f/5$ or slightly faster, and $f/18$–$f/20$ focal ratios for spectroscopic work at the Cassegrain focus. Direct photography, not typical before 1950 with such instruments, could be done at the prime focus using Ross lenses to correct for coma, a defect in reflectors that stretches images away from the optical axis. Ritchey and Henri Chrétien proposed an alternative scheme which combined a near-parabolic primary with a hyperbolic secondary and a concave photographic plate. This arrangement produced a wider field but was a difficult combination to fabricate. Ritchey built two examples, but the system did not come into its own until much later. Another way to obtain a wider field was the catadioptric arrangement, combining both lens and mirror. The first such instrument was BERNHARD SCHMIDT's photographic telescope, developed from 1931. The SCHMIDT TELESCOPE combined a spherical primary with a specially ground corrector lens. The lens compensated for both spherical aberration and coma, although it did produce a slight chromatic aberration. As the image produced is a curved plane, the photographic film had to be curved. Such a combination allowed for a very fast, short-focal-length system with a wide field for

Dirac House, Temple Back, Bristol, BS1 6BE, UK

photography. By 1948, two such instruments were at work at Palomar Mountain; the larger, with a 48 in corrector plate, was central to the National Geographic Society–Palomar Observatory Sky Survey.

Other specialized instruments catered to solar astronomy. Hale was a leader in designing solar telescopes, beginning with a horizontal arrangement at Yerkes and Mount Wilson. Later, he developed vertical solar telescopes with pairs of optical flats to reflect sunlight downwards to a primary. By reducing thermal currents, this was an effective method for spectroscopy. To observe the corona, Bernard Lyot invented the CORONAGRAPH in 1930, an instrument that blocked the solar disk and largely eliminated scattered light from the optical system.

Throughout this period, other technological innovations increased the power and improvement of these large instruments. Production of moving parts requiring a high degree of precision stretched the capabilities of mounting manufacturers. Steel replaced cast iron for the major parts of tubes and mountings. Steel torsion rods to maintain the rigidity of tubes gave way to Mark Serrurier's truss tube in the 200 in telescope. Relief from the increasing weight of polar axes and the need for smooth motion required roller bearings in the late 19th century. Common and Ritchey experimented with mercury flotation. Plaskett's substitution of self-aligning ball bearings became standard for large reflectors, but the 200 in telescope's designers, concerned about weight, opted for oil pad bearings.

Temperature maintenance was also important. Ritchey introduced a diaphragm above his primary mirrors along with blankets and others chose similar methods and a variety of insulation materials. Small electric heaters were introduced into spectrographs. Weight-driven clock drives were eventually superseded by electrically synchronized driving systems. Better photographic emulsions allowed for faster photography and extended spectral coverage. Experiments with aluminizing mirrors showed the method's superiority to silver by the early 1940s. The introduction of workable photoelectric photometers made photometry an exact science. Still, in this pre-computer age, the quality of astronomical work depended on astronomers with great skill at controlling these giants.

Telescopes were not only for professionals. Amateur astronomers, in growing numbers in the early 20th century, purchased both refractors and reflectors of modest aperture from a variety of manufacturers. Reflectors, being easier to make, became the focus of a substantial amateur telescope-making fraternity in the United States from the 1930s. Access to affordable but high-quality telescopes allowed amateurs throughout the world to make significant contributions to astronomy with lunar, planetary and variable-star observations.

The telescope stands as the technological icon for astronomy in much the same way the microscope does for biology. Although it appears to be a deceptively simple optical device, the telescope, through advances in engineering, optical design and materials (see TELESCOPE ENGINEERING), has become one of the most sophisticated modern scientific instruments. Telescopes have always been expensive; by the time the 200 in telescope saw first light, the telescope had become symbolic of the newly emergent 'Big Science'.

Thom, Alexander (1894–1945)

British engineer and archaeo-astronomer, born in Scotland, became professor of engineering science at Oxford University. Accurately surveyed the megalithic sites in Britain and the megalithic lunar observatories, identifying their shapes and astronomical alignments. He claimed to have discovered in the dimensions of the circles, as apparently used by the megalithic constructors, quanta of length that he called the megalithic yard and megalithic inch. Possibly he over-interpreted the data

Thomson, William [Baron Kelvin of Largs] (1824–1907)

Born in Belfast, Ireland, became professor of physics at Glasgow, studied thermodynamics, proposed an absolute scale of temperature, measured by the *Kelvin temperature scale*. In parallel with HERMANN VON HELMHOLTZ, he formulated a theory of stellar evolution, in which a star radiated the energy that it released by progressive gravitational contraction. The lifetime of a star from this theory (the time over which its gravitational potential energy is radiated from its surface) is the *Kelvin–Helmholtz time scale* and proved to be too short to be compatible with the geological age of the Earth.

Three-body Problem

The three-body problem, i.e. the problem of finding the motions of three gravitating bodies moving under their mutual gravitational attraction, was studied by Isaac NEWTON in an attempt to explain the motion of the Moon.

In the general three-body problem three bodies of arbitrary mass start from an arbitrary initial configuration and move purely under the inverse square force of attraction. There is no general analytical solution, other than series expansions, to this problem since typically the orbits are chaotic.

The progress leading to our current understanding of the problem has taken centuries and the efforts of leading mathematical physicists such as Euler, Lagrange, Jacobi and Poincaré, to mention a few classical ones. In 1772 LAGRANGE found many special solutions of the problem (such as the equilateral triangle solution), while Jacobi studied the circular restricted three-body problem where one body is of negligible mass and the two others describe a circular orbit about their common center of mass. In this article we concentrate on the astrophysical aspects of the stellar three-body problem and purposely neglect many of the mathematically interesting solutions which, in fact, have physical realizations only in planetary systems (i.e. systems with large mass ratios). The existence of chaos in the three-body problem was already the conjecture of POINCARÉ in 1899, and that has been amply confirmed by recent works.

One may divide the astrophysically interesting three-body systems into three main categories:

(a) Systems of stars (of comparable masses and initial distances) that break up after some dynamical evolution. Such configurations are typical in star forming regions (see STAR FORMATION).
(b) Scattering of single stars off CLOSE BINARY STARS. These events are important in the dynamics of STAR CLUSTERS.
(c) Stable hierarchical systems, examples of which are the numerous triple stars observed in the galactic field.

(See also CELESTIAL MECHANICS.)

Close initial configurations

The first attempts at actually solving the orbits of the three bodies date from the early twentieth century. Sundman constructed a (formal) series solution which converges for all times, but the solution is useless in practice due to extremely slow convergence. The first published attempt to integrate numerically orbits of three masses was made by Burrau. He performed an orbit integration of a special problem which is usually called Burrau's problem. There three bodies of masses 3, 4 and 5 units start at rest from the corners of a Pythagorean triangle such that the mass values scale with the lengths of the sides opposite to the body in question.

Without computers Burrau was able to calculate only a short stretch of the orbits; the complete calculation was performed by Szebehely and Peters in 1967. Figure 1 illustrates the complete orbit solution.

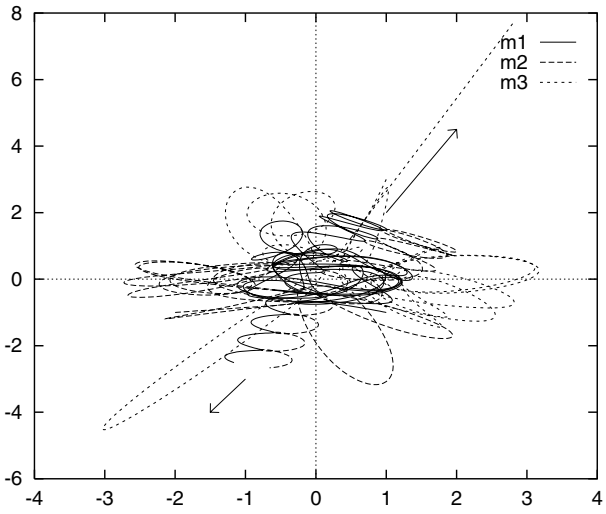

Figure 1. Burrau's three-body problem.

Even though this particular problem has no special astrophysical significance, it illustrates well a typical solution of the three-body problem: as a rule, close approaches of two of the bodies occur while the third body is at a somewhat greater distance. Often the third body goes so far away that the other two bodies form a temporary binary. This situation is called *ejection*. At other times all bodies stay close to each other and perform repeated close encounters at frequent intervals. This type of motion is called *interplay*. When one of the members of a temporary binary is replaced by another body, we call the event *exchange*. Finally, one of the bodies leaves the binary permanently, in which case we have an *escape*. In figure 1 a single body moves to the upper right, and the binary to the lower left at the time of the escape.

The escape times in a large number of bound triple systems occur at random, in the manner of radioactive decay. They are best described by the half-life of the triple system. The lifetime of Burrau's system prior to the escape is about 20 times the period of the initial temporary binary, and this is in fact a rather typical value for the half-life in general.

After the escape the orbits can be approximated by Keplerian two-body orbits for all future times. The binary is essentially described by its two masses, its semi-major axis and its eccentricity. The relative motion of the binary and the third body is described by the escape velocity at infinity of the third body. If we only need to know this final asymptotic state of the three-body problem, then the solutions can be stated in a simple way.

In astrophysics, the finite sizes of the bodies are also of importance. Close approaches between the bodies may lead to collisions of the celestial bodies, or at least various frictional forces may come into play. If the bodies are surrounded by tenuous outer layers or disks, the latter

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

may be stripped away during the close approaches. The distance of the closest two-body approach is not known in advance but can be estimated statistically. In case of Burrau's problem the shortest distance is 4×10^{-4} units, about 0.01% of the original dimension of the system. Typically only 1% of all similar three-body systems have approaches closer than this.

Statistically the final states of the three-body systems after the escape may be described by the approximate analytical theory of Heggie and Monaghan. One starts by writing out the energy E_0 of the three-body system after the escape as

$$E_0 = \frac{1}{2}\frac{m_s m_B}{M}\dot{\boldsymbol{r}}_s^2 + \frac{1}{2}\frac{m_a m_b}{m_B}\dot{\boldsymbol{r}}^2 - G\frac{m_a m_b}{r} \qquad (1)$$

where bodies of mass m_a and m_b form a binary and the body with mass m_s is the third body which will be considered an escaper. The binary mass is written $m_B \equiv m_a + m_b$ and the total mass of the system $M \equiv m_B + m_s$. The separation vector between the binary members is $\boldsymbol{r}$ and the third body is at separation $\boldsymbol{r}_s$ from the binary centre of mass. G is the gravitational constant. Equation (1) is an approximate expression valid for very large separations of the the binary and m_s (the potential energy due to interaction of the binary and m_s has been neglected).

It is now assumed that the probability of a given end state of the system is proportional to the volume of the phase space available for escape. The density of the end states σ per unit energy is

$$\sigma = \int \cdots \int \delta\left(\frac{p_s^2}{2m} + E_B - E_0\right) \mathrm{d}\boldsymbol{r}_s\, \mathrm{d}\boldsymbol{p}_s\, \mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{p} \qquad (2)$$

where $m = m_s m_B/M$, E_B is the energy of the binary, and $\boldsymbol{p}$ and $\boldsymbol{p}_s$ are the canonical momenta associated with $\boldsymbol{r}$ and $\boldsymbol{r}_s$.

When equation (2) is integrated over $\boldsymbol{r}_s$ and $\boldsymbol{p}_s$ we obtain the statistical distributions for the binary. Correspondingly, we may integrate over $\boldsymbol{r}$ and $\boldsymbol{p}$, and obtain the distributions for the escaper. After carrying out the appropriate normalizations the main results are:

(a) The binary eccentricity e is distributed as

$$f(e)\,\mathrm{d}e = 2e\,\mathrm{d}e \qquad (3)$$

in a three-dimensional system and

$$f(e)\,\mathrm{d}e = \frac{e\,\mathrm{d}e}{\sqrt{1-e^2}} \qquad (4)$$

in two-dimensional systems.

(b) The probability that the escaper is the body with mass m_s is given by

$$f(m_s)\,\mathrm{d}m_s = \frac{m_s^{-2.5}\,\mathrm{d}m_s}{m_s^{-2.5} + m_a^{-2.5} + m_b^{-2.5}}. \qquad (5)$$

(c) The binary energy E_B is distributed

$$f(E_B)\,\mathrm{d}E_B = 3.5|E_0|^{3.5}|E_B|^{-4.5}\,\mathrm{d}E_B \qquad (6)$$

$|E_B| \geq |E_0|$. More accurate theories show that the power -4.5 of $|E_B|$ is approximate (the correct one depends somewhat on masses and is $3 + \sqrt{13}/2 \approx 4.8$ for equal masses). From equation (6) it is straightforward to calculate the distribution of the escape velocity V_s:

$$f(V_s)\,\mathrm{d}V_s = 3.5\frac{m_s}{|E_0|}V_s\left(1 + 0.5\frac{m_s}{|E_0|}V_s^2\right)^{-4.5}\mathrm{d}V_s. \qquad (7)$$

Equations (3)–(7) constitute the complete statistical solution of the unstable three-body problem when the three bodies are initially in a bound state.

Scattering off a binary

The above equations are applicable also in the case of scattering of a single body from a hard binary (i.e. the total energy $E_0 < 0$). Then one may often consider that a temporary bound state, a *resonance*, has formed and that the break up of the resonance state follows the standard statistical theory.

In STELLAR DYNAMICS one often encounters situations where the binary is not hard. The theory of soft-binary scattering has been derived using the assumption that the third body approaches one of the components of the binary to a distance which is much less than the semi-major axis of the binary, and such that the motion of the third body relative to this component is approximately unperturbed by the other binary member during the most important part of the encounter. After averaging over all relevant variables one obtains a cross section for a change in the binding energy of the binary, for an exchange of binary members, or for a complete disruption (*ionization*) of the three-body system. The applicability of the analytic theory has been tested by large numbers of numerical scattering experiments.

The results from the scattering theory may be expressed as follows: let the third body of mass m_s come from infinity with the asymptotic velocity V_s relative to the binary center of mass, and let the (positive) binding energy of the binary be x. After the scattering the binding energy has changed to a value $x + y$. Then the differential cross-section $\mathrm{d}\Sigma/\mathrm{d}y$ for an energy change of magnitude y is

$$\frac{\mathrm{d}\Sigma}{\mathrm{d}y} = 4\pi G^2 \frac{m_a m_b m_s^2}{m_B}\frac{1}{V_s^2 y^2}F(x, y) \qquad (8)$$

where

$$F(x, y) = 1 - \frac{4}{3}\frac{x}{y},\ y < 0 \qquad (9)$$

$$F(x, y) = \left(\frac{4}{3}x + \frac{7}{3}\right)\left(\frac{x}{x+y}\right)^{5/2},\ y > 0. \qquad (10)$$

Equation (8) may be integrated over y to obtain the total cross section Σ, for example, for ionization or for

capture, i.e. for the formation of a resonance. Usually the result is expressed relative to πa^2 where a is the semi-major axis of the binary.

The expression is simplified by using the critical velocity V_c, defined by

$$\frac{1}{2}mV_c^2 = \frac{Gm_am_b}{2a} \tag{11}$$

which is the critical incoming velocity of the third body making the total energy equal to zero (i.e. we have $E_0 = 0$ when $V_s = V_c$). Using this formalism the cross section for ionization becomes ($V_s \gg V_c$)

$$\Sigma_{\rm ion} = \pi a^2 \frac{40}{3} \frac{m_s^3}{m_a m_b M} \frac{V_c^2}{V_s^2}. \tag{12}$$

Corresponding expressions have been derived for the cross sections of capture and exchange.

A convenient semi-empirical expression for the differential cross section for energy exchange in case of equal masses and hard binaries was given by Spitzer (1987)

$$\frac{{\rm d}\Sigma_{\rm tot}}{{\rm d}\Delta} \approx \pi a^2 \frac{13.7V_c^2}{V_s^2} \frac{1}{\Delta^{1/2}(1+\Delta)^4}. \tag{13}$$

Here $\Delta = y/x$, and the approximation includes the effects of both resonant interactions and distant fly-bys. The expression is valid for $\Delta > 0$, which is by far the the most typical case for hard binaries (i.e. binaries with binding energy much larger than the typical kinetic energy of single stars).

Hierarchical triplets

In hierarchical triplets there is a binary well isolated from the third body which is in a closed orbit (outer binary orbit) about the center of mass of the binary (inner binary). Such configurations are stable if the pericenter of the outer orbit is distant enough from the binary: typically the pericenter distance must satisfy the inequality $q_{\rm min} \geq 3a$, but the exact value depends on the masses and orbital elements.

The interesting property of such systems is that the secular perturbations by the distant third body transform the inner binary orbit. In 1962 Kozai considered the secular perturbations of asteroids due to Jupiter, and the predictions of this analytical theory constitute what is now known as the *Kozai mechanism*. There occurs a long-period, cyclical exchange of angular momentum between the third body and the binary.

One of the most interesting results is that the eccentricity e and inclination i of the inner binary oscillate and can have large amplitudes, provided that the initial inclination of the outer orbit relative to the binary plane is high enough. In particular, if the initial inclination $i = 90^\circ$, the system evolves to $e \to 1$ and a collision between the binary members takes place. The length of the eccentricity cycle is of the order of $P_{\rm out}^2/P_{\rm in}$, where $P_{\rm out}$ is the period of the outer binary and $P_{\rm in}$ the period of the inner binary.

Numerical methods

The orbits of three-body systems are generally extremely sensitive to changes in initial conditions. Thus numerical calculations must be done with high accuracy. Nowadays most numerical integrations of three-body systems utilize regularization by the Kustaanheimo–Stiefel transformation. For studies of long-term evolution of hierarchical systems symplectic methods are also available, which do not produce secular errors in constants of motion.

Bibliography

The three-body problem is dealt with in most textbooks on celestial mechanics, which generally deal with the restricted three-body problem and the Lagrangian solutions.

Thorough treatments of the three-body problem are found in:

Marchal C 1990 *The Three-body Problem* (Amsterdam: Elsevier)

Szebehely V 1967 *Theory of Orbits. The Restricted Problem of Three Bodies* (New York: Academic)

More recent works of interest include:

Tides

Everyone who has lived near the ocean is very much aware of the variation in the level of the ocean water that is called the *tide*. On nearly all days there are two high tides and two low tides, and the astute observer will notice that these extreme tides occur about fifty minutes later on the average than they did the day before. The fact that the MOON reaches its maximum elevation above the horizon with the same average 50 min delay on each successive day makes it logical to suspect the Moon as the cause of our observed ocean tide.

In contrast to their awareness of the ocean tide, few people know that the solid body of the Earth also experiences a tide with an amplitude of about 30 cm. This motion is not at all obvious, as all objects on the solid surface of the Earth move together, just as the ocean tide would not be obvious to an observer on a ship in midocean. But the solid-body tide is detectable with sensitive instrumentation. There is even an atmospheric tide on the Earth that is detectable with a simple barometer. However, this tide is caused by the absorption of radiant energy from the SUN rather than gravitational effects, where the atmospheric tide on the Earth caused by the latter is negligible by comparison.

The Moon interacts with the Earth through gravitational force, and one can generalize the idea that the Moon is responsible for the Earth tide to every SOLAR SYSTEM object: each planet or satellite in the Solar System experiences tidal distortions due to all the other objects attracting the planet or satellite gravitationally. As a first test of this hypothesis, we expect the Sun to also raise a tide on the Earth, and we observe that it does. The Earth tide due to the Sun is not as large as that due to the Moon, but it is quite noticeable when one considers that the highest and lowest tides occur when the Sun and Moon are nearly lined up—a time when they both pull on the Earth in the same or opposite directions. It is easy to follow the heights of the local tidal extremes in newspapers of any coastal city where these extremes are maximal at new and full Moon.

Below, we show how the tidal deformation of a body is caused by differences in the gravitational forces exerted by the disturbing body on different parts of the disturbed body, develop a simple physical model with which we can describe the essential features of tidal distortion, and indicate the conversion of tidal energy into heat as the tide oscillates. It is this change of mechanical energy into heat that allows slow changes in the orbits and rotations of many objects in the Solar System, and we discuss what some of the consequences of such tidal evolution have been for each planet and their satellites, if any. Tidal forces also affect stars, star clusters, galaxies, clusters of galaxies, etc that we discuss briefly, but we shall limit most of our examples to the easily observable consequences in the Solar System. We end by pointing out current frontiers of research.

Theory of tides

We are all familiar with gravity as the force that attracts us and all other objects to the Earth. An object dropped near the Earth's surface accelerates toward the center of the Earth at the rate of 980 cm s^{-2}. However, the acceleration of the Moon toward the Earth is only 0.27 cm s^{-2}, as this is the acceleration necessary to keep it moving in its almost circular orbit. From these two numbers, we find that the acceleration of gravity is proportional to $1/r^2$, where r is the separation of the centers of the two bodies that are being attracted to each other—either the Earth and Moon or the Earth and the object we drop. We also know that if we double the mass of an object, that is, double the amount of material in it, the force of gravity on the object is doubled. It is twice as heavy, but since the acceleration of an object is inversely proportional to its mass (force = mass × acceleration is Newton's second law), the acceleration in the Earth's field remains the same. But we see that the force of gravity on a body must also be proportional to its mass. By observing the orbital motions of the satellites about the MAJOR PLANETS (just as we observed the Moon about the Earth), we can infer that the force of gravity must be proportional to the mass of the attracting object as well, leading to the expression for gravitational force between two spherically symmetric bodies,

$$F = Gm_1m_2/r^2$$

where G is the constant of proportionality called the gravitational constant. This law of universal gravitation was also discovered by NEWTON.

A gravitational field of force of a Solar System object leads to a distortion of another massive object that is in the field because the force decreases as the distance from the source of the field increases. This means that different parts of the object in the field experience different gravitational forces. This is illustrated in figure 1, where the forces on the small mass elements due to the satellite of mass m are represented by arrows at three points on the planet M. The separation of M and m is represented by r, and the radius of the planet is R. If ΔM is the mass of each element indicated on M, the gravitational force due to m on that element is given by

$$\Delta F = \frac{Gm\Delta M}{x^2}$$

where x is the actual distance of ΔM from the center of m. The fact that ΔF decreases as x increases from $r-R$ to $r+R$ is indicated in figure 1 by the decrease in the length of the arrows from the points x_2 to x_c to x_1. As the acceleration of each ΔM is $\Delta F/\Delta M$, from Newton's second law, we see that the side of M closest to m tends to accelerate more toward m than the center, and the center tends to accelerate more than the far side. If the masses (ΔM) of the elements at x_1, x_c, and x_2 were completely free from one another, x_2 would move away from x_c toward m, and x_1 would be left behind by x_c. Relative to x_c, the two points x_1 and x_2 would accelerate in opposite directions at rates indicated in the

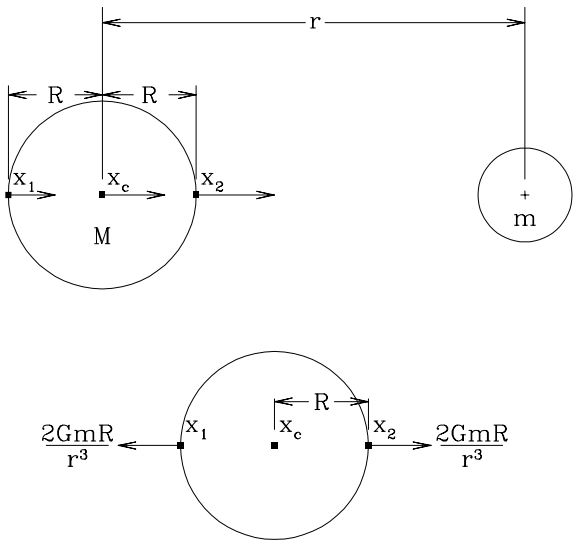

Figure 1. How the decrease in gravitational acceleration with distance from the perturbing mass m leads to differential tidal accelerations on the perturbed body M.

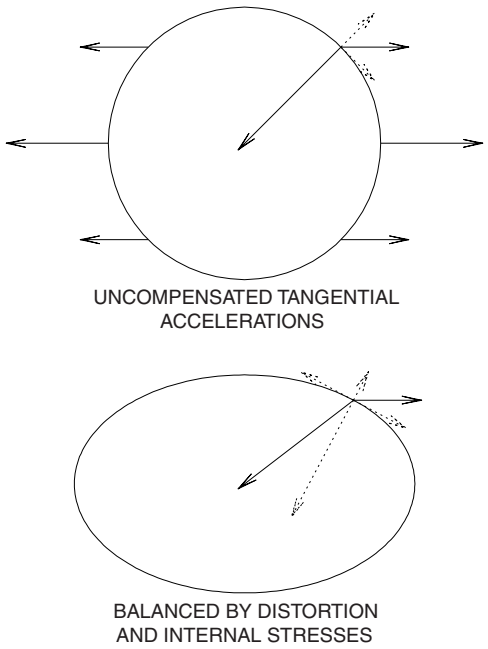

Figure 2. Distortion of a planet to bring it into equilibrium with an external gravitational field.

bottom part of figure 1. These differential accelerations tend to stretch M into a prolate ellipsoid, similar to the shape of an egg, and they depend on the inverse cube of the separation r because they are the differences of two forces that depend on $1/r^2$.

But the ΔMs are not free, since they are attracted gravitationally to one another and to the remaining mass in M. The accelerations toward the center of M due to self-gravity acting on the ΔMs at x_1 and x_2 are far stronger than the differential accelerations shown in figure 1, so mass does not fly off the surface at x_1 and x_2. If the material in M were incompressible, the ΔMs at x_1 and x_2 would weigh less than they would if m were not there, but one might suppose that the ΔMs would not move relative to the center. But M will still distort into an egg shape unless it is perfectly rigid as well as being incompressible. (When acted on by forces, an incompressible substance preserves its volume but may change shape, whereas a *perfectly* rigid substance does not change shape.) The reason is that points in M that do not lie on the line joining the centers of M and m also experience a differential acceleration relative to x_c. But now the differential accelerations are not perpendicular to the surface and are therefore not compensated by the self-gravity that accelerates mass elements more or less toward the center of M. This is shown in figure 2, where the differential acceleration at one point is resolved into its equivalent components perpendicular and tangential to the surface. These components are shown as dashed arrows and are equivalent to the solid arrow, in that together the forces they represent produce the identical acceleration. The self-gravity, shown as an arrow directed toward the center of M in the top part of figure 2, compensates the vertical component of the differential acceleration but not the tangential component. If M were entirely fluid, the uncompensated tangential components of the differential accelerations would cause fluid to flow toward the points on M closest to and furthest from m, until M would resemble the bottom part of figure 2. In this ellipsoidal shape, the self-gravity is now no longer perpendicular to the surface but has a tangential component opposite to that of the differential acceleration due to m. Only in the distorted shape are all the differential accelerations compensated and the whole planet is accelerated like the center at x_c.

If M is not fluid but is rigid like rock, part of the compensating acceleration is provided by internal stresses, and the distortion is not as large as it would be for a fluid. Still, no material is perfectly rigid, so there is always some tidal bulge. All materials are at least somewhat compressible as well, and the expansion of M in the directions where the weight of overlying material is reduced by the presence of m accentuates the tidal distortion. Note that the tidal distortion is independent of the velocity of M relative to m and would occur either if M and m were in a stable orbit or if they were simply falling toward each other. There is no need to invoke centrifugal force to account for the tidal bulge on the side of M furthest from m, although this has often been done in erroneous explanations of tidal deformation. (We limit our discussion to a simple tidal bulge whose size and orientation depends on the system properties and geometry. Practitioners of tidal theory find it expedient to decompose the simple bulge into a sum of separate tides with distinct frequencies and geometries. This

decomposition is a mathematical convenience that is not necessary for understanding the essential features of tidal theory and evolution.)

We are now in a position to understand the main features of the Earth tides, given that the Earth tends to be distorted into an egg shape which is aligned toward the Moon and into a lesser distortion aligned toward the Sun. First, from the bottom part of figure 1, the differential magnitudes of the solar and lunar tides follow from the expression for the differential acceleration which is proportional to m/r^3. The lunar mass is much smaller than the solar mass, but it is so much closer to us that the r^3 in the denominator more than compensates for the tiny mass and results in a lunar tide about twice the magnitude of the solar tide. The ocean tide rises and falls at a given point on a coast because the Earth rotates under the Moon. The tidal bulge tends to stay more or less aligned with the Moon, so for our fixed position on the *rotating* Earth, we are carried through alternate high and low points of the tidal deformation. The high tides occur when we pass under the Moon and when we are on the opposite side of the Earth from the Moon, and low tides occur when we see the Moon rise or set. Hence, there are two high and two low tides each day. The ocean tide is obvious to us on a coast because the solid Earth is rigid and distorts less than the fluid ocean.

Close observation reveals that the ocean tide is more complex than the simple picture we have just presented. The high tide can occur at times considerably removed from the time the Moon reaches its maximum elevation above the horizon. This is because the continents interrupt the free passage of the tide. The ocean basins are like giant bathtubs in which the water likes to slosh with a period of oscillations given by $w/\sqrt{gd}$, where w is the width of a given ocean, d is the average depth, and g is the acceleration of gravity at the Earth's surface. This period is comparable to the half-day tidal period, which means the reflection of the tidal wave off a continental boundary and the resulting sloshing of the ocean water can result in high tides occurring at odd times relative to the lunar position in the sky. As an example, high tide occurs about two hours *before* the Moon reaches its highest point in the sky at Santa Barbara, California. Long narrow bays can also change the times of various tidal phases relative to the Moon's position. Only the Earth has such a substantial ocean interrupted by continents, so all other Solar System bodies are more likely to conform to the situation where their tidal bulges are nearly aligned with the direction to the tide raising body. This simplicity is extremely useful when we consider the dissipation of tidal energy in a more or less solid satellite or planet with no complicating ocean.

We pointed out earlier that the lunar tide on Earth is about twice as large as the solar tide because this is the ratio of the corresponding differential accelerations or forces causing the tide. In other words, for the small tidal amplitudes observed, the amplitude is proportional to the disturbing force. This is exactly the way a spring behaves—the stretch is proportional to the stretching force.

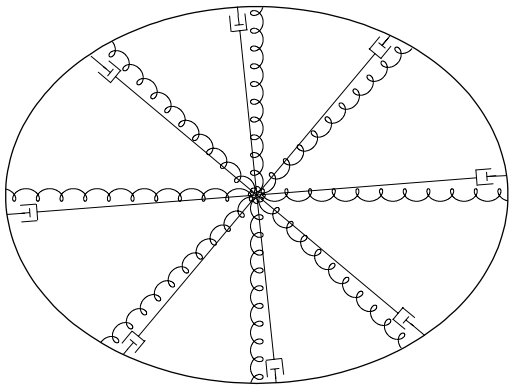

Figure 3. Idealized representation of a solid, elastic planet by a collection of springs. A fluid planet can be similarly represented except the restoring force of the springs is purely gravitational instead of elastic. Here the planet is shown distorted by an external field.

So we can represent a solid satellite or planet now as a collection of springs such as that shown in figure 3, where the restoring force of the springs is a combination of gravity and elasticity of the material. (For a fluid planet the restoring force would be all gravitational as in figure 2.) As the planet or satellite rotates relative to the tide-raising body, the springs are alternately stretched and relaxed. No material is perfectly elastic, so part of the energy stored in the stretched spring is converted to heat. This conversion of energy is represented by the dashpots attached to each spring in figure 3. (A *dashpot* is a device for turning the kinetic energy of motion of a mass at the end of a spring into heat. It can be thought of as a leaky piston in a cylinder of oil where the oil is 'dashed about' as the piston moves. An everyday example of a dashpot is the shock absorber on an automobile.) The springs follow the forcing term, that is, reach their maximum stretch when the differential acceleration is greatest, if the period of variation of the disturbing force at a given point on the body is sufficiently long compared to the shortest natural period of oscillation of the body. On the Earth, the period of variation of the disturbing force is, on average, half the time between moonrises, whereas the Earth 'rings' when struck by a large earthquake with periods like an hour. This condition of slow variation of the tides compared to natural periods of oscillation is satisfied on all the Solar System objects subject to tidal deformation.

The dissipation of mechanical energy (conversion into heat) causes each spring to reach its maximum stretch slightly after the maximum force is applied by analogy to a damped harmonic oscillator, of which a mass on the end of a spring with dashpot is the classical example. This means that for a planet or satellite (M in figure 1) uncomplicated by the interaction of oceans with continents and bays, the high tide follows the perturbing body m, but it occurs at a point after m has passed overhead. The amount of the time delay in the response of the spring representing the planet or satellite is proportional to the amount of dissipation per

Copyright © Nature Publishing Group 2001

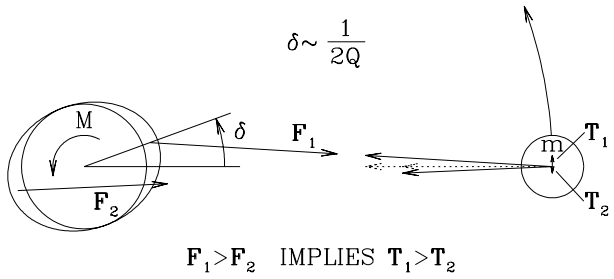

Figure 4. Consequences of dissipation of tidal energy, where the spin of M is being retarded while m is being accelerated in the direction of its orbital motion.

oscillation cycle when this dissipation is small. If we define the dissipation function Q by

$$Q = \frac{2\pi E_0}{\Delta E}$$

where E_0 is the maximum energy stored in a tidal oscillation and ΔE is the energy dissipated (mechanical energy turned into heat) in a complete cycle, the time delay in the response is proportional to $1/Q$.

This time delay caused by energy dissipation has an interesting consequence shown schematically in figure 4. The bodies m and M are reproduced as in figure 1, except M is shown tidally distorted and rotating relative to m. (There is a similar distortion and perhaps a rotation of m that we shall ignore for the time being.) The fact that the maximum tide occurs at a point on M after m has passed over that point means that the tidal bulge is displaced in the direction of rotation relative to a line to m. Here we assume the rotation of M and the orbital motion of m are in the same direction and that the spin angular velocity of the former is larger than the orbital angular velocity of the latter. If the orbital motion were faster, the bulge would be displaced in the opposite direction. The angle δ by which the tidal bulge leads is equal to $1/2Q$. Since low Q implies high dissipation, δ increases with dissipation. The tidal bulges are about equal in size, but again because the gravitational force decreases as $1/r^2$, the bulge nearest m experiences a greater force from m than the one further away. These unequal forces $\boldsymbol{F}_1$ and $\boldsymbol{F}_2$ are represented by the arrows (*vectors*) of unequal length. (The arrows are drawn in the directions of the forces.) The first consequence of this inequality results from the fact that the forces are not directed through the center of M. Since $\boldsymbol{F}_1 > F_2$, a twisting effect or torque is exerted on M in a direction which retards the spin angular velocity. Since the size of the tidal bulges is proportional to m/r^3 and the torque on the bulges is also proportional to m/r^3 (again the difference of two $1/r^2$ forces), the torque on M due to tides raised by m is proportional to m^2/r^6.

Forces equal to F_1 and F_2 but opposite in direction are exerted on m (Newton's third law). These are represented by the appropriate vectors in figure 4 drawn from the center of m. These forces are resolved into two components, one directed toward M and one perpendicular to that direction. These components are shown as dashed vectors in figure 4. The reaction forces on m can be replaced by these components to produce the same accelerations of m. The components in the direction of M just contribute to the much larger central attraction responsible for the orbital motion. Since $\boldsymbol{F}_1 > F_2$ then necessarily $\boldsymbol{T}_1 > \boldsymbol{T}_2$ (figure 4). This acceleration of m causes it to spiral away from M as the latter's spin angular velocity is reduced.

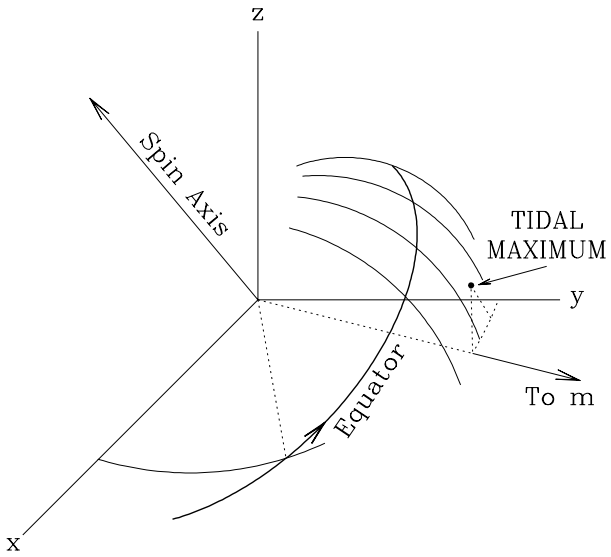

Figure 5. If the equator of M is inclined to the orbit plane, the tidal bulge is carried out of this plane resulting in torques that change the direction of the spin axis in addition to retarding the spin magnitude.

In figure 4, we assume m to be orbiting in the equatorial plane of M. However, if the spin axis of M is not perpendicular to the orbit plane of m, the tidal bulge is carried out of the plane of the orbit by M's rotation, as illustrated in figure 5. This results in a torque on M that is not parallel to the spin axis. Part of the torque tends to tilt the spin axis and part tends to change the spin magnitude. By this means, the obliquity (angle between the spin axis and a line perpendicular to the orbital plane of m) is changed. There is a corresponding but much smaller change in the orbital plane.

In the isolated two-body case discussed so far, as long as there is any rotation of either M or m relative to the other, which includes the cases where either the obliquity or orbital eccentricity is not zero, torques result that cause the orbit and spins to change. If a rapidly spinning planet is very massive compared to a single satellite that orbits in a relatively close circular orbit, the satellite is relatively quickly slowed to SYNCHRONOUS ROTATION by large tides raised on the satellite by the planet, as the tides raised on the planet by the satellite increase the radius of the satellite's orbit. The planet's spin slows only a little because of its large mass. If the orbit is eccentric, tides

on the satellite tend to drive its spin to a value that is slightly larger than the synchronous rotation. The tide is largest at the periapse of the orbit (point of closest approach), where the now non-uniform orbital angular velocity is maximal. The spin would then tend toward that value where the tidal torque, averaged around the orbit, vanishes, and this occurs at a spin angular velocity that is less than the maximum orbital angular velocity at periapse but larger than the mean orbital angular velocity. Why then is the Moon rotating synchronously with its mean orbital angular velocity in spite of being in a slightly eccentric orbit where tides raised on the Moon by the Earth are trying to make the spin slightly larger? This is because the Moon, or any other satellite, is not axially symmetric. It has a permanent effective egg shape (supported by internal stresses as are large mountains on Earth) that is much larger than that induced by the tide, and the tidal torque from the Earth on this permanent deformation dominates that on the gravitationally induced tide, forcing the long axis and hence the same face of the Moon to point toward the Earth every time the Moon passes the periapse of its orbit, where the tidal force is maximal. This can be true only if the Moon rotates at a rate synchronous with the *mean* orbital motion—not at the slightly larger rate where the tides would take it.

Dissipation of tidal energy still occurs in a synchronously rotating satellite in eccentric orbit, since the tides wax and wane in magnitude as the orbital distance changes, and the position of the tidal maximum rocks back and forth on the satellite because the satellite rotates uniformly whereas the orbital motion is not uniform. As the eccentricity is the cause of this dissipation, the dissipation will lead to a decrease in the eccentricity. At the same time, the tide raised on the rapidly rotating planet by the satellite will try to increase the eccentricity. Recall that the tide and hence the torque ($\propto m^2/r^6$) is maximal when the satellite is at the periapse of its orbit. The greater tidal force on the satellite at this point (T_1 in figure 4) tends to fling the satellite to a greater distance at its apoapse (the furthest point in the orbit) than it would have gone without the kick—thereby increasing the eccentricity. Which effect wins depends on the magnitude of the rate of dissipation in the satellite versus that in the planet (i.e. on Q_m/Q_M).

Now consider a satellite in a circular orbit that is spinning rapidly relative to the synchronous rate and having a non-zero but small obliquity (equatorial plane inclined to the orbit plane). Here the tide raised on the satellite tends to drive the obliquity to larger values. This is best understood if we represent the spin as a vector having a component parallel to the orbit plane and another perpendicular to the orbit plane. The tidal torque is reducing the magnitude of perpendicular component at all points in the orbit, whereas it does not reduce the parallel component when that component is pointing toward or away from the planet. Averaged around the orbit, the fractional decrease in the perpendicular component exceeds the fractional decrease in the parallel component, and the spin vector represented by the components has been tilted more. There is an equilibrium obliquity between 0° and 90° toward which the spin is driven where the *fractional* decreases per orbit in the two components of the spin are equal. This equilibrium obliquity is near 90° if the satellite spins very rapidly, but decreases toward 0° as the spin slows from the tides. For a spin angular velocity less than $2n$ (twice synchronous), the equilibrium obliquity is 0°, so a satellite in a fixed circular orbit should approach synchronous rotation and zero obliquity simultaneously.

If the planet and satellite are of comparable mass, both planet and satellite can approach synchronous rotation and zero obliquity as the orbit expands. Once neither planet nor satellite are rotating rapidly relative to the orbital mean motion, the tides on both bodies eventually tend to reduce the eccentricity. So the natural endpoint of tidal evolution in this case is both bodies synchronously rotating in a circular orbit with both equatorial planes coincident with the orbital plane.

Other outcomes of tidal evolution include a satellite's spiraling into the planet or its disintegration by tidal forces, or perhaps by collisions, to form a ring of material in the planet's equatorial plane (see PLANETARY RINGS). Some of the many rings of small-mass objects orbiting in the equatorial planes of the major planets could have had their origin through a tidal disintegration of a larger, rubble pile type object. Multi-satellite systems exhibit a rich collection of orbital resonances where the mean orbital angular velocities are near the ratio of small whole numbers, and most of these were most probably assembled by differential tidal expansions of initially more random orbits. Within the resonances, continued tidal evolution forces increasing eccentricities and/or orbital inclinations relative to a planet's equatorial plane. In *nearly* all real cases, the rate of tidal evolution is so slow that the logical endpoint of that evolution, where no further changes will occur, has not been reached nor will it be reached before the Solar System ceases to exist as we know it some 5×10^9 yr from now. We examine some of these real situations in the examples below, where some of the remaining puzzles of tidal evolution are also pointed out.

We can summarize tidal theory as follows:

(1) Tides are raised on a Solar System body M by differences in gravitational forces across the body due to any nearby body m (figures 1 and 2).
(2) Any relative rotation between M and m causes the tides and hence the internal stresses to oscillate. This causes some of the tidal energy to be converted into heat much like the heating of a paper clip that is bent back and forth repeatedly or the warming of a liquid in turbulent flow.
(3) The tides resemble damped harmonic oscillators (mass on the end of a spring spanned by a dashpot) in many ways (figure 3), where forcing the oscillator at a period that is long compared to the natural period of free oscillation results in a time lag in the response of the oscillator relative to the forcing term. The maximum of a tide at a point on the distorted body

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

then occurs after the tide-raising body has passed overhead (figures 4 and 5).

(4) The resulting non-alignment of the tidal bulges with the tide-raising bodies results in torques that decrease the relative rotations while changing the separation between the bodies. The separation of two tidally interacting bodies, the obliquities of their spin axes, and the eccentricity of their mutual orbit all change in predictable directions governed by the geometry, spin magnitudes relative to the mean orbital angular velocity, and the dissipation factors Q of each object.

(5) For rapidly spinning planets with a satellite in prograde orbit, the most obvious tidal evolution is a reduction in the spins of both planet and satellite toward rotation that is synchronous with the orbital mean angular velocity as the orbit is expanded.

Consequences of tidal evolution

The differential tidal force and the dissipation of tidal energy described above are responsible for many observed phenomena in the Galaxy and universe. Individual stars are stripped from galactic and GLOBULAR CLUSTERS of stars if the star drifts into a position where the differential tidal force exerted by the total galactic mass exceeds the gravitational force of the other cluster members attracting the star toward the cluster. COMETS are stripped off the Oort cloud of comets that is thought to extend beyond 10 000 astronomical units from the Sun (an astronomical unit (AU) is the distance from Earth to Sun). Weakly bound comets or ASTEROIDS can be broken up by tidal forces as they pass very close to a planet—as was probably demonstrated by the disintegration of Comet Shoemaker–Levy 9 before the spectacular crashes of the pieces into Jupiter in 1994 (see SHOEMAKER–LEVY 9–JUPITER COLLISION). CLOSE BINARY STARS are synchronously rotating with their circular orbital motion, due to retardation of their spins and damping of their orbital eccentricities from the torques arising from the dissipation of tidal energy. The same tidal mechanism may have circularized the orbits of extra-solar planets (EXOPLANETS) discovered orbiting very close to their respective parent stars. Great streams of stars, dust and gas are observed trailing away from a galaxy after being ripped from that galaxy by tidal forces exerted by another galaxy that has passed very close. All of these examples, except the synchronously rotating binary stars, are the results of singular events where transient circumstances lead to relatively short timescale dominance of tidal forces. The Solar System offers many more immediate examples where dissipation of tidal energy over the age of the Solar System has led to very interesting and sometimes spectacular consequences. We shall consider each planet and planet–satellite system in turn to point out how the system has been altered by tides.

Mercury

MERCURY experiences tides raised by the Sun, and sufficient time has elapsed for Mercury's spin to have been slowed to a rate synchronous with its orbital mean angular velocity. It therefore came as quite a surprise when radar observations by Pettengill and Dyce in 1965 revealed Mercury's rotation period to be only two-thirds of its orbital period. The eccentricity of Mercury's orbital ellipse has the rather large value of 0.206. Because of this high eccentricity, Mercury can rotate stably at several values of rotational angular velocity that are half-integer multiples of its mean orbital angular velocity. These particular rotational states are stabilized by the average torque on the *permanent* axial asymmetry. This asymmetry is like a tidal bulge, except it is not induced by an exterior gravitational field but is supported by internal shear stresses. The stability is such that the long axis of the permanent, egg-shaped asymmetry is oriented toward the Sun as Mercury passes through the perihelion (point in orbit closest to the Sun) of its orbit. This same stability was pointed out above as a necessary condition for synchronous rotation of a satellite in an eccentric orbit.

The inferred tidal evolution of Mercury's spin angular velocity is a tidal retardation of the spin through a series of stable states, where the spin angular velocity $\dot{\psi}$ would be $3n$, $2.5n$, $2n$, or $1.5n$, where n is the mean orbital angular velocity. These spin angular velocities would allow the long axis of Mercury's slight egg shape to be nearly aligned with the direction from Mercury to the Sun at every perihelion passage. Such a state is stable against further tidal evolution if the maximum average torque on the permanent deformation exceeds the tidal torque. Mercury need not be captured in a stable state as it passes through. The probability of capture depends on the detailed tidal model, but all tidal models share the property that the states corresponding to the spin angular velocity $\dot{\psi} = An$, where A is a half-integer, have a decreasing probability of capture as A increases, ultimately reaching zero probability when A is so large that the state is not stable. Thus we find Mercury in that spin state ($\dot{\psi} = 1.5n$) which has the highest capture probability of any state Mercury could have passed through as the tides slowed it toward synchronous rotation. Observations of an intrinsic magnetic field on Mercury imply the existence of a conducting liquid core. If this core were liquid early in Mercury's history, the tidal evolution may not have been as described here. The existence of a liquid core with the resulting dissipation of energy through any differential rotation with respect to Mercury's mantle drastically increases the probability of capture into the spin–orbit resonances. If capture of Mercury into the 2:1 spin–orbit resonance were certain because of the core–mantle interaction, Mercury may have had to start its rotation with $\dot{\psi} < 2n$. Mercury is the only example known where such spin–orbit coupling has led through tidal evolution to a stable state other than synchronous rotation.

But tidal dissipation is still occurring in Mercury, making the orbit more circular. The stability of the current spin state vanishes when the orbital eccentricity gets sufficiently small. Tides could thus eventually bring Mercury to synchronous rotation in a nearly circular orbit.

However, it would take many times the age of the Solar System for this to occur.

That Mercury's spin axis is very close to being perpendicular to its orbital plane (nearly zero obliquity) is also a result of tidal evolution. However, because Mercury's orbit is not fixed, but precesses relative to the stars with a period of about 250 000 yr due to the gravitational perturbations by the other planets, the tides are trying to drive Mercury's spin toward an orbit normal (vector perpendicular to the orbit plane) that is itself moving. The compromise position to which the spin is driven is called a Cassini state, where the spin axis lies permanently in a plane determined by a line perpendicular to its orbital plane and a line perpendicular to the plane of the Solar System. This state is very close to the orbit normal, and Mercury would have been driven there by the tides from virtually any initial obliquity and spin angular velocity.

Venus

VENUS rotates in a direction which is opposite to the sense of its nearly circular orbital motion. This state is described by assigning an obliquity ϵ of nearly 180° to the spin axis. This retrograde rotation is not the result of tidal evolution in the ordinary sense of tides raised by the solar gravitational field, since such tides attempt to drive the obliquity to zero after Venus's spin rate became less than $2n$. If Venus began with an obliquity greater than 90°, like Uranus whose obliquity is 97°, the friction between a liquid core and the solid exterior of Venus called the mantle could dominate the ordinary gravitational tide and drive Venus to the current 180° obliquity. If Venus started with $\epsilon < 90^\circ$, the core–mantle interaction would have aided the gravitational tide in driving Venus eventually toward zero obliquity. In this case the only alternative to account for the current $\epsilon \simeq 180^\circ$ seems to be an atmospheric thermal tide. There is reason to suspect that such a thermal tide exists on Venus, since we observe one on Earth. The absorption of solar radiation in our upper atmosphere couples with the modes of oscillation of our atmosphere to generate an egg-shaped distribution of atmospheric mass whose maxima occur at 10:00 a.m. and 10:00 p.m. local time. With this phase, the gravitational attraction of this thermal tide by the Sun tends to accelerate the spinning atmosphere and thereby the EARTH'S ROTATION. This is opposite to the effect of the gravitational tide which is decelerating the Earth. The effect of the atmospheric thermal tide on the Earth's spin is only about 10% of the effect of the gravitational tide. But Venus's atmosphere has nearly 100 times the mass of our own atmosphere, so if a similar thermal tide is generated on Venus, it may easily dominate the gravitational tide. If we can model that tide by a gravitational tide but simply reverse the torque on the planet, the atmosphere could dominate both the gravitational tide and a core–mantle interaction and drive Venus to its current obliquity from a primordial obliquity less than 90°. Observation of the barometric pressure at the surface of Venus for a Venus day would determine the magnitude of the current thermal tide and probably indicate whether or not the atmosphere was capable of turning Venus upside down.

Earth

Tidal evolution of the Earth–Moon system has been directly measured. Our day is getting longer at the rate of about 0.0016 s each century. The Moon's mean orbital angular velocity is decreasing at the rate of about 22 arcseconds per century[2]. This means that each year, the Moon is moved further away from us by about 3 or 4 cm. This rate implies an Earth which is currently more dissipative than it was in the past, for if we extrapolate the Moon's orbit backward in time, assuming the Earth's Q was always its current value, the Moon ends near the Earth's surface only 1.6 Gy ago—about one-third the age of the Earth–Moon system (1 Gy is 10^9 yr). Most of the tidal dissipation on Earth is in the oceans, and the higher Q in the distant past is usually attributed to a different configuration of the continents, thereby allowing for fewer shallow seas for the dissipation of the tidal energy.

The effect of the tide raised on the Moon by the Earth has driven the Moon's rotation to the endpoint of its tidal evolution consistent with the current orbital configuration. The Moon's rotation is synchronous with its mean orbital motion, which we readily ascertain by always viewing the same lunar face from Earth. In addition, its spin axis has been driven to a stable Cassini state, in which the spin remains coplanar with the perpendiculars to the Moon's and Earth's orbit with an obliquity of $6^\circ 41'$. (The current geometric configuration of the Moon spin axis together with its synchronous rotation are collectively called Cassini's laws, from which the name Cassini state is derived.)

Although tidal dissipation in the Moon has been sufficient to slow it to synchronous rotation and drive the spin axis to a Cassini state, the contribution of the tidal heating to the thermal history of the lunar interior has been negligibly small. The Moon was, of course, once much closer to the Earth, and the rate of dissipation was correspondingly much higher than it is now. However, it was pushed out too fast toward distances corresponding to small dissipation for the interior to heat significantly.

Mars

MARS' spin has not been significantly affected by tidal dissipation. It is too far from the Sun, and its satellites, PHOBOS AND DEIMOS, are very small. The two satellites, on the other hand, are both rotating synchronously with their orbital mean motions. The inner satellite, Phobos, is unusual in the sense that it is so close to Mars (orbit radius $\simeq 6.8$ Martian radii) that its orbital period is less than Mars' rotation period (7.65 h versus 24 h 37 m). Reference to figure 4 shows that in this case the tidal bulge is behind Phobos and the direction of acceleration of the satellite is opposite to its motion. Phobos is therefore spiraling into Mars. The measured acceleration of Phobos' orbital angular velocity leads to a Q of Mars of about 100, which is comparable to that of rocks on the Earth. If Q remains

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the same as Phobos spirals toward Mars *and* if Phobos is sufficiently strong to remain in one piece, it will strike the surface of Mars in about 10^9 yr.

Jupiter

JUPITER is about 300 times more massive than Earth, and its satellites, although three of them are larger than our Moon, total only a little over 10^{-4} of Jupiter's mass. The spin of the planet has thus not been significantly altered by the tides.

The satellites have experienced significant tidal evolution. All the Galilean satellites (discovered by Galileo)—Io, Europa, Ganymede, and Callisto—are rotating synchronously with their respective orbital motions, as is Amalthea, which is a small satellite inside the innermost Galilean satellite, Io (see JUPITER: SATELLITES). The orbits have not expanded very far, however, since Io is only about 5 Jupiter radii from the planet's surface. This close proximity after 4.6×10^9 yr of evolution means the averaged Q of Jupiter must exceed about 6×10^4.

The first three Galilean satellite orbits have mean orbital angular velocities that obey the relation $n_1 - 3n_2 + 2n_3 = 0$ (called the Laplace relation), where the subscripts refer to IO, EUROPA and GANYMEDE respectively. Io's angular velocity is nearly twice Europa's and Europa's nearly twice Ganymede's. The satellites are stably locked together in these orbital resonances, and so their orbits must expand together while maintaining the relation among their mean orbital angular velocities as tides raised on Jupiter push them away. It is likely that the differential tidal expansions of the orbits assembled the satellites into the resonances.

The existence of the orbital resonances has had a profound effect on Io. The condition that conjunctions of Io and Europa (both satellites on the same side of Jupiter at closest approach) always occur when Io is at the periapse of its orbit, forces the eccentricity of Io's orbit to the value of 0.0041. Even though Io is synchronously rotating with its mean orbital motion, the tide raised on Io by Jupiter increases and decreases in magnitude and the bulge moves back and forth to follow the motion of Jupiter in Io's sky. Io rotates uniformly, whereas the orbital motion in an eccentric orbit is not uniform. This causes the oscillatory motion of Jupiter in Io's sky. The tide raised on Io is enormous—more than 7 km high if Io were fluid and uniformly dense. The variable part of the tide is 100 m for this fluid Io, so one expects substantial tidal dissipation. (Taking account of Io's central condensation reduces these tidal amplitudes somewhat, but they remain enormous.) Ordinarily such dissipation would damp the orbital eccentricity to zero, and the dissipation would cease. However, the eccentricity is maintained by the tides raised on Jupiter continuously trying to force Io deeper into the orbital resonance, and the accumulated heat has been sufficient to melt the entire satellite. Tidal theory was used to predict that Io should be extensively melted, and the VOYAGER spacecraft subsequently found it to be the most volcanically active body in the Solar System. This is a case where tidal dissipation has dominated all other energy sources in determining the thermal history of a Solar System body.

Saturn

SATURN, like Jupiter, has not evolved significantly through tidal interaction (see SATURN: SATELLITES). But all the satellites out to and including IAPETUS are rotating synchronously with their orbital mean motions, with the exception of HYPERION, as a consequence of tidal dissipation. Recent detection of albedo features on the surface of TITAN through a narrow infrared window in its perpetual atmospheric haze have verified its synchronous rotation. Voyager 2 images have shown Hyperion to be slowly rotating and therefore tidally evolved in spite of its small size. However, Hyperion is so far from spherical symmetry and is in such an eccentric orbit that strong gravitational torques on the satellite due to Saturn prevent an evolution to an orderly synchronous rotation. Hyperion will most likely tumble in a chaotic fashion for the remaining lifetime of the Solar System.

There are three sets of orbital resonances among the satellites of Saturn that were known before Voyager 1 and several more among the recently discovered smaller satellites. Of the former resonances, the 2:1 resonances between MIMAS and TETHYS and between ENCELADUS and DIONE could have been assembled by differential tidal expansion of their orbits. However, the 4:3 Titan–Hyperion resonance could have been so assembled only if the Q of Saturn was considerably smaller for the tide raised by Titan on Saturn compared to the Q appropriate to the inner satellites. Even if this were true, Titan's mass is so large that special circumstances would have had to prevail to allow its orbit to expand to the 4:3 resonance with Hyperion without close approaches that would eliminate Hyperion from the system. The proximity of Mimas to Saturn establishes the lower bound $Q \geq 16\,000$ for Saturn. A lower Q would have pushed Mimas farther away from the planet than we find it. This value of Q is too high to allow the evolution to the observed state of Titan–Hyperion resonance from an initial condition appropriate for a presumed tidal assembly. As there are no obvious reasons for imposing a sufficient amplitude or frequency dependence on Q to preserve both the tidal assembly of the inner resonances and that of Titan–Hyperion, it is often assumed that the latter resonance must be linked to the formation process and therefore not due to tidal evolution.

Observations by Voyagers 1 and 2 showed that the surfaces of several satellites had been reworked by some indigenous processes after the major cratering events. Especially puzzling is Enceladus, which is an icy satellite only 250 km in radius but which has areas on its surface that are probably less than 10^9 yr old. The radioactive content of Enceladus is negligibly small, and application of the tidal heating hypothesis, which was so successful in accounting for the state of Jupiter's satellite Io, does not supply sufficient energy to cause the resurfacing, given the eccentricity of 0.0044 maintained by the resonance with Dione. Still, tidal heating, by a process of elimination,

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

seems to be the only viable source of energy to cause the relatively recent resurfacing of Enceladus. If this is so, then Enceladus must have participated in one or more orbital resonances in the relatively recent past that could force its eccentricity to large values, thereby dissipating sufficient tidal energy to soften its interior. Earlier resonances, since disrupted, with Tethys and with the small moon Janus have been proposed, but there is no consensus on the details of the orbital history.

Uranus

URANUS is too far from the Sun and its satellites too small for the dissipation of tidal energy to have affected its spin. However, the five largest satellites, MIRANDA, ARIEL, UMBRIEL, TITANIA, and OBERON, in order of distance from Uranus, appear to be synchronously rotating with their orbital motion as predicted by tidal theory. (The largest satellite, Titania, has a radius of about 805 km and a mass of about 3.3×10^{24} g, where the latter is about 4.5% of the lunar mass.) The satellite system is unlike those of Jupiter or Saturn as none of the satellites is involved in an orbital resonance. However, it is almost certain that such resonances existed in the past, since some of the satellites have apparently been resurfaced by indigenous processes and the innermost of the five larger satellites, Miranda, has an unusually large inclination of its orbit relative to Uranus's equatorial plane of 4.2°. (Logical formation processes would start Miranda and the other close satellites in equatorial orbits.) The only reasonable way to account for this inclination is to have Miranda pushed into a 3:1 orbital resonance with Umbriel by tides raised on Uranus where the inclination secularly increases to a point where the resonance is disrupted leaving the inclination at its high value. There are remaining puzzles in the Uranus system whose explanations most probably involve the dissipation of tidal energy, but details of the resonance history are still uncertain. Ariel, the next satellite out from Miranda, has been resurfaced since crater counts are drastically reduced in places. Ariel is currently outside the 2:1 orbital resonance with the next satellite, Umbriel, but an orbital eccentricity sufficiently high to have softened the interior of Ariel might have been forced by occupancy of this resonance in the past. However, the 2:1 resonance is difficult to disrupt, and we would expect this resonance to persist if it had ever existed. If the 2:1 resonance never existed, the tidal expansion of Ariel's orbit is limited to the range outside this resonance. This places an lower bound on the Q of Uranus of 11 000, while at the same time, the necessity that Miranda had occupied the 3:1 resonance with Umbriel to account for its orbital inclination places a upper bound on this Q of 39 000. (If $Q < 11\,000$, Ariel's orbit would have expanded sufficiently to have begun inside the 2:1 resonance with Umbriel, whereas if $Q > 39\,000$, Miranda's orbit would not have expanded far enough to have begun inside the 3:1 resonance with Umbriel.) Still, the 2:1 Ariel–Umbriel resonance may have been disrupted by the perturbations of Titania through some subtle resonance interaction yet to be discovered. A final puzzle is that Umbriel's surface is uniformly very old, whereas that of Titania, which is outside Umbriel, has been resurfaced in places. An interesting tidal history of this satellite system remains to be discovered.

Neptune

Prior to the Voyager spacecraft reconnaissance in 1989, NEPTUNE's known satellite system consisted of one large satellite, TRITON, in a close, circular but retrograde orbit (orbiting in a direction opposite to the sense of the rotation of Neptune) and a small satellite, Neried, in a distant, prograde but highly eccentric orbit. Triton is the only example in the Solar System where such a large satellite orbits in a retrograde sense so close to its primary (14.33 Neptune radii). The only plausible explanation for this unusual orbit is that Triton did not form in the same way that the regular satellites of the other major planets had formed by the accumulation of debris in the equatorial plane of the forming planet, but that it was formed elsewhere in the Solar System and captured by Neptune in a highly eccentric, but retrograde orbit, where the capture was most likely accomplished through collision with previously orbiting debris. The damping of the high eccentricity would be accomplished by tidal dissipation from tides raised both on Neptune by Triton and on Triton by Neptune. (Note that the retrograde orbit reverses the usual tendency of the tides on the planet to increase eccentricity.) Tidal theory was used to predict this history before the Voyager encounter, and it placed some severe constraints on what we expected to find from the Voyager images. First, evidence of tidal heating would be revealed by a very young Triton surface with few or no craters. Second, Triton would have cleaned out all small satellites for some distance outside its current orbit. Voyager found Triton to be nearly crater-free, and although 6 small new satellites were found orbiting in Neptune's equatorial plane inside Triton's orbit, none were found outside.

Pluto

Pluto is a binary planet in the sense that its satellite, Charon, is of comparable size (Pluto radius ∼1500 km, Charon radius ∼700 km) (see PLUTO AND CHARON). The discovery of the satellite occurred fortuitously just before the orbital motion of the system swept the orbital plane past the Earth. Repeated occultations and eclipses involving Pluto and Charon resulted in a detailed description of the system. The orbital period is 6.3867 d—the same as Pluto's rotation period. It is also almost certain that Charon is also synchronously rotating with the orbital motion, making the system the only example in the Solar System where tidal evolution has progressed to its logical endpoint. The only possible exception to this conclusion is that the orbital eccentricity may not be quite zero, although observations implying the latter have not been independently confirmed.

Future research

We have pointed out several puzzles of tidal evolution of the satellite systems in the Solar System that await resolution using essentially the tidal theory outlined above coupled with theories of orbital resonances. An implicit assumption in this theory is that the tides change slowly enough that their magnitudes are assumed to have the values a static tide would have. However, the circularization of the orbits of the recently found extra-solar giant planets orbiting within 0.2 AU of their stars presents a special problem. If these planets were formed far from their stars and their present close orbits involved scattering by a close encounter with another giant planet in the system, the orbit initially would have been highly eccentric with a very small periapse distance. Such a scenario requires that the eccentricity be damped in a time less than the estimated age of the central star—presumably by tidal dissipation. But both the planet and the star are essentially completely gaseous where ordinary schemes of dissipating tidal energy, such as turbulence, are very inefficient. Until recently, only one scheme, involving a phase change in helium in the deep interior, had been offered to account for sufficient dissipation in Jupiter to account for the tidally maintained set of resonances among the Galilean satellites, and it is uncertain whether conditions prevail that would allow the mechanism to work. However, the distribution of gas in a giant planet as well as that in a star are subject to various modes of oscillation whose frequencies ordinarily would have been thought sufficiently high that the standard tidal treatment would suffice. An example where this assumption is not appropriate is the thermal tide on the Earth, where the excitation is diurnal, but the major response is semi-diurnal. Treatment of an atmosphere disturbed by a varying tidal force due to rotation apparently requires a dynamic rather than a static tidal treatment, where the atmospheric response is resolved into a series of oscillation modes. Application of such an analysis to Jupiter has accounted for sufficient dissipation to accommodate the maintenance of the satellite resonances, although, again, a special structure that might not prevail is required. The frontier of tidal theory thus lies in the development of analyses that account for the full dynamics of gaseous bodies. The major motivations are to obtain rates of tidal dissipation in gaseous bodies that are theoretically secure, which give dissipations in the giant planets within observational bounds, and which could account for the circularization of the orbits of extra-solar planets close to their stars.

Time Scales: Atomic

Atomic time scales (ATSs) are here considered; in the next section the historical reasons that led to an atomic definition of the second, adopted by the XIIIth Conférence Général des Poids et Mesures (CGPM) in 1967, are given. The Comité Consultatif Temps et Fréquence (CCTF), meeting every 3–4 yr at the Bureau International des Poids et Mesures (BIPM), now performs studies on the Système Internationale (SI) atomic second and on the ATSs, in Paris.

In the subsequent section the main characteristics of a time scale (TS) are reviewed along the resulting requirements, while the final section deals with the theoretical and practical construction of TAI (Temps Atomique International (INTERNATIONAL ATOMIC TIME)) and UTC (UNIVERSAL TIME Coordinated), the TS on which the entire everyday life of all nations is regulated.

Attention is drawn to the fact that the letter 'C' in UTC denotes 'coordinated' and not 'coordinate'; UTC is not a time coordinate in a relativistic meaning, but is the result of a coordinated effort by parts of most of the national metrological institutions. Each institution keeps a local version of TAI (K), where the K in parentheses is the name of the individual laboratory, the expression TAI being usually reserved to the International Time Scale, as calculated by the Time Section of BIPM, on the basis of the readings of the individual clocks kept in the participating laboratories. UTC (K) differs from TAI by an integer number of hours and represents the time reference scale to be used inside a given country; with the notation UTC is intended the realization of this TS in the 0 time zone, around the International Meridian of origin.

The atomic definition of the second and the concept of an atomic time scale

In the middle of the 20th century, for a number of applications the accuracy, precision and stability of the second, as the unit of time interval, were not adequate. Their requirements of scientific applications—lunar radar ranging, spectroscopy research—and technical ones—telecommunications and electronic instrumentation—were not met by the astronomical definitions, reaching relative accuracies between 10^{-7} and 10^{-8}.

At NPL, England, in 1955 a frequency standard using a cesium transition was put in operation: this device offered an accuracy of some 10^{-9} and led to a number of discoveries, one of which was the first measurement of the secular decrement in the speed of EARTH'S ROTATION.

The definition of the 'atomic' second

The present definition of the second is based on a microwave transition of cesium (the official definitions are in French): 'Le seconde est la durée de 9 192 631 770 périodes de la radiation correspondant à la transition entre les deux niveaux hyperfins de l'état fondamental de l'atome de césium 133'.

The value given for the cesium hyperfine transition frequency was obtained by a measurement of cesium frequency in terms of the second of Ephemeris Time; in these terms the atomic SI second can be considered as linked to an astronomical unit, based on the Earth's revolution.

The atomic time scale

A TS is fully identified by two choices:

- the unit of scale, i.e. the time interval to be accumulated and numbered—in the case of TAI this interval is the SI second;
- the origin.

The choice of the origin is fully arbitrary and is a matter of agreements and of convenience; the origin was chosen as 0 hours UT1 on 1 January 1958.

The first definition of TAI, translated in English, is as follows: 'International atomic time (TAI) is the time reference coordinate established by the Bureau International de l'Heure on the basis of the readings of atomic clocks operating in various establishments in accordance with the definition of the second, the unit of time of the International System of Units' (in 1988, the responsibility of TAI was transferred from the Bureau International de l'Heure to the Time Section of the Bureau International des Poids et Mesures).

This TAI definition adopted by CGPM in 1971 was enlarged in 1980 by CCTF (at that time the name was CCDS—Consultative Committee for the Definition of the Second) in order to take in to account relativity effects: 'TAI is a coordinate time scale defined in a geocentric reference frame with the SI second as realized by the rotating geoid as the scale unit'.

In this situation, the relation between the TAI scale unit and a given realization of the SI second as given by an atomic clock depends on the position of that clock. For clocks at rest, and situated at sea level, the scale unit of TAI is equal to the unit of time, the SI second, as realized locally. The scale unit of TAI appears to be longer by 2.2×10^{-13} s if compared with a clock kept at an altitude of 2000 m, owing to the gravitational redshift. A complete theoretical definition of TAI in the framework of general relativity can be found in the documents of the IAU General Assembly held in Buenos Aires, 1991 (Resolution A4); see also REFERENCE FRAMES AND TIME SCALES IN GENERAL RELATIVITY.

TAI is consequently an artificial TS, formed by combining with suitable algorithms the readings of atomic clocks kept in metrological laboratories or other scientific institutions in different geopotential conditions.

Characteristic of a time scale

The features that must be exhibited by a TS—as for most of the units and standards of physical quantities—are many and in some cases unexpected.

ATSs adequately fulfil some of these requirements but are completely lacking as regards others. The requirements are accuracy, precision, stability, universality (access availability) and perenniality.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

Some links between these properties, their scientific use and the relevant consequences are outlined in what follows.

Perenniality
The ATS being based on artefacts, this property cannot be satisfied. Any ATS given by an individual clock is bounded by the technical life of that clock and consequently cannot be extended in the past and in the future, as is indeed possible—at least in principle—with all the astronomical TSs.

It is worth noting that the ATS of a single atomic clock is not everlasting or perennial, but ATSs based on agreements, such as TAI itself or TT (Terrestrial Time; see also TIME SCALES: TERRESTRIAL), can be mutually linked to former TSs, in order to ensure perenniality.

The general lack of perenniality and the need to perform time links between clocks or TS calls for three features, as regards the formation of an ATS:

- redundancy of clocks, also inside a laboratory;
- availability of accurate time comparison systems, inside a laboratory and between remote laboratories, to perpetuate the 'reading' of a failing clock;
- geographic or topographic 'dispersion' of these clocks to reduce the consequences of any mishap regarding the clocks of a given laboratory.

These three characteristics to be satisfied inevitably have profound consequences for TS formation.

Universality
This characteristic had a physical meaning in the pre-relativity era; now the term is intended to mean that an ATS is accepted, accessible and made available to all classes of users. These three characteristics are studied and obtained by some international scientific unions (UAI, URSI), scientific–technical bodies such as CIPM, via its CCTF, and BIPM, via its Time Section, and technical–regulatory bodies, such as ITU-R (International Telecommunication Union—Radiocommunications).

Accuracy
The time 'length', or duration of the second used to construct an ATS, must conform as strictly as possible to the SI definition. This agreement, estimated to be around 10^{-9} in 1955, when the first atomic frequency standard was put in operation, is progressing by about 1 order of magnitude per decade. At the turn of the century this agreement reached an accuracy of some 10^{-14} and it is expected that an additional 1–2 orders of magnitude could be at reach. ATS accuracy can be considered to be satisfactory.

It is important to stress that this level of accuracy is available 'nearby' the clock and cannot easily be transferred to remote locations.

Precision
This is a measure of the ability to 'read' the date of an event. Precision depends on the characteristics both of the atomic clock (its phase noise) and of the instrument. Another obvious limitation exists if the reference ATS is to be remotely accessed via a link, rather than being available in the same laboratory where the timing is to be performed.

Stability
This characteristic is taken for granted (at least as regards the flow of time); no experiment so far performed has cast doubts on the temporal stability of Planck's constant or of fine or hyperfine constants.

No variation has been observed at the level of 10^{-14} yr^{-1}.

Time scales from pulsars or other astronomical objects
The lack of perenniality of a TS based on manmade devices has promoted, since 1975, the search for clock references in the universe; this research so far has offered no solutions to TS formation for scientific and technical timing but has provided some useful information about these extraterrestrial time reference sources.

Atomic time scale formation

General consideration on time scale characteristics and requirements
ATS formation is a very complicated affair and it is definitely not a trivial one. The reasons for these complexities can be grouped into at least five categories:

(a) final goals;
(b) characteristics of the clocks;
(c) characteristics of the comparison systems between the remote clocks;
(d) problems intrinsic to any averaging systems;
(e) how to evaluate relativity effects, black-body radiation effects, etc and how the uncertainty budget of primary clocks is established.

A few examples are given for the five categories.

(a) Should the final ATS strive for uniformity and stability or for accuracy?
These goals can be conflicting: navigation systems are more interested in stability; fundamental constants research is more interested in accuracy.
(b) Each kind of atomic clock is affected by different noise processes, very seldom 'white': see 'Noise processes affecting atomic clocks' below.
(c) The various comparison systems exhibit different 'errors' and noise processes, or phenomena linked to the propagation or environmental temperatures; the 'time constants' required to compensate for these effects can be in conflict with the 'time constants' inside the algorithms chosen to optimize accuracy or stability.
(d) The 'colors' (the spectral behaviour) of some noise affecting the clocks can prevent an easy statistical

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

treatment; moreover, how should the time constant be used, what time constant should be used and how should the clocks contributing to the TS be weighted?

(e) The accuracy of a primary atomic clock cannot be measured with reference to another primary clock; it can only be estimated. To determine the error budget of one of these clocks is an operation based on the intellectual honesty of the experimenters.

Another problem, a technical and organizational one and typical of TAI formation, is how to collect timely data from some 200 atomic clocks, of different types, kept in some 50 laboratories scattered around the world. Similar problems are encountered for the TS of navigation systems or formed in national metrological institutions.

Formation algorithms

As an example, the formation of TAI, a two-step process, is described. Initially, using a weighted mean of all the clocks, a TS called EAL is formed, from the French échelle atomique libre—free atomic time scale. EAL is optimized for long-term stability and its frequency is, with a suitable time constant, corrected in a way to conform to the frequency of the cesium primary frequency standards. Adopting this two-step process, both stability and accuracy can be secured, clearly within some given limits. Obviously some criteria to be followed in establishing the weights of the individual clocks must be adopted.

The average TS EAL can be defined as follows:

$$\mathrm{EAL} = \frac{\sum_{i=1}^{N} p_i[h_i(t) + h_i'(t)]}{\sum_{i=1}^{N} p_i}$$

where $h_i(t)$ represents the reading of the ith clock , taken at time t, N is the number of atomic clocks, p_i is the statistical weight of the ith clock and $h_i'(t)$ is a suitable correction needed to offer continuity in time and in frequency in the case of the introduction or removal of a clock or the change in weight of a clock, while

$$x_{ij} = h_j(t) - h_i(t)$$

is the measure of the difference between the clocks.

A system of N equations in N unknowns is formed; the results are the wanted differences between the average EAL and the readings of the individual clocks.

Noise processes affecting atomic clocks

One of the subtlest problems in TS formation is the consequences for the reading of a clock due to various noise processes affecting the frequency and the phase of the real devices. This problem is of paramount importance in satellite navigation systems in which the mutual discrepancy between the some 50–100 atomic clocks forming a given system should be kept, at any time, below 1 ns. Half of these clocks are placed in orbiting satellites and must be kept on time by a complex system of monitoring stations, which are also required to determine, in real time and using time measurements, the position of each satellite with errors less than 1 m.

A number of problems, such as the choice of the orbit, the kind and number of atomic clocks kept on Earth or in space, the adoption of a given synchronization technique and the number and the geographic positions of the monitoring stations, are all linked to the noise processes affecting the clocks. The reading of any clock is indeed divergent as a result of the noise processes, and to keep this discrepancy against the TS formed by the entire navigation system inside 1 ns requires a frequency accuracy of the order of 10^{-14} and the most accurate synchronization techniques.

The law of divergence of the reading of an individual clock against the 'average' depends on the kind of noise and, in some cases, the divergence and its estimate are not linear with the elapsed time, as can be seen in table 1.

Table 1. Divergence of clock readings for various kinds of noise.

Kind of noise	Uncertainty prediction $u(t)$: law of proportionality to the elapsed time
White noise on phase	t^0
Flicker on phase	$[\ln(t)]^{1/2}$
Random walk on phase	$t^{1/2}$
Flicker frequency	t
Random walk on frequency	$t^{3/2}$

Uncertainties

Accuracy can be secured only by a comparison with primary cesium frequency standards, where 'primary' means that an uncertainty budget was obtained via a number of experiments and calculation.

At the present state of knowledge an accuracy of a few 10^{-15} seems within reach, provided that a suitable integration time is adopted.

Time Scales: Terrestrial

Terrestrial time is at present derived from atomic clocks. The SI second, the unit of time of the international system of units, has been defined since 1967 in terms of a hyperfine transition of the cesium atom and the best primary frequency standards now realize it with a relative uncertainty of a few parts in 10^{15}, which makes it the most accurately measurable physical quantity. INTERNATIONAL ATOMIC TIME (TAI) is based on more than 200 atomic clocks distributed worldwide that provide its stability, while a small number of primary frequency standards provide its accuracy. From TAI is derived Universal Coordinated Time (UTC) that is the basis of all legal time scales. To allow the construction of TAI and the general dissemination of time, clocks separated by thousands of kilometers must be compared and synchronized. This may be achieved with an uncertainty of a few nanoseconds in 1 day or less using radiotransmission techniques such as the Global Positioning System (GPS) or two-way time transfer using geostationary satellites. The definition of TAI must be considered within the framework of general relativity; it is a realization of a time coordinate in the geocentric reference system. In the future a new generation of clocks may provide, in the laboratory or on board satellites, an accuracy of 10^{-17} or less. When this happens it may be necessary to reconsider both the definition and the way of realizing TAI and new time transfer techniques will need to be developed to compare the new clocks.

Relativity: proper and coordinate time

Relativity distinguishes locally measurable (proper) quantities from coordinates which are, by definition, dependent on conventions. Therefore one should distinguish proper time, which is the output of an ideal clock, from coordinate time, which is one of the coordinates chosen to represent the four-dimensional space–time. In its Resolution A4 (1991), the INTERNATIONAL ASTRONOMICAL UNION explicitly introduced general relativity as the theoretical background for space–time reference frames (see also REFERENCE FRAMES AND TIME SCALES IN GENERAL RELATIVITY). For the geocentric system, it defined two time coordinates: the geocentric coordinate time (TCG) and terrestrial time (TT), which differs from TCG by a constant rate so that the scale unit of TT agrees with the SI second on the geoid. In this framework, it is clearly stated that TAI is a realization of TT (apart from a constant offset of 32.184 s). That relativistic point of view had already been adopted by the Consultative Committee for the Definition of the Second[1] (CCDS) which declared (1980) 'TAI is a coordinate time scale defined in a geocentric reference frame with the SI second as realized on the geoid as its scale unit'.

[1] Now named the Consultative Committee for Time and Frequency (CCTF).

Generation of an atomic time scale

According to a definition of the International Telecommunications Union, a time scale is an 'ordered set of time markers'. To form an atomic time scale, the efficient combination of the readings of the atomic clocks requires the definition of the expected qualities of the time scale, the characterization of the timing data and the design of an algorithm (see TIME SCALES: ATOMIC). In addition to the basic requirement that a single time marker be attributed to one event, one may consider metrological qualities for a time scale, such as its stability and accuracy, or practical qualities such as its reliability and delay of access.

Stability may be defined by the ability to keep the same frequency over a given time interval. A number of statistical tools have been devised to estimate the instability of a clock or time scale (or more generally any time series of measurements). Among them, the most commonly used is the two-sample, or Allan, deviation $\sigma_y(\tau)$, which estimates the fractional frequency instability over the averaging time τ. Figure 1 presents the frequency stability of various recent clocks and that of TAI for comparison. Accuracy, on the other hand, may be defined as the degree of conformity of a value to its definition. At present the SI second is defined by a hyperfine transition of the Cs atom, and only a few laboratory devices, the primary frequency standards, aim at realizing it with utmost accuracy. The most accurate primary standard is now a Cs fountain developed at the LPTF in Paris, which states a frequency accurate to 2×10^{-15}. All clocks that are not so specially designed may be very stable but display various degrees of inaccuracy. To be accurate, an atomic time scale must therefore be compared with one or several primary standards.

A single atomic clock may provide a time scale, but it is always subject to failure. To increase the reliability, redundancy is necessary. This may simply consist in replacing a failed clock by another one, after proper synchronization of the clocks during their common operation. However, combining the data of several clocks to form a time scale will improve the stability, accuracy and reliability with respect to those of a single clock. To reach this goal, a suitable stability algorithm must be used. This approach, which is adopted by many metrology laboratories and operation centers for navigation systems, has been the basis of the construction of TAI since its inception. While the readings of one atomic clock are available in real time, an ensemble time scale may be designed to be available in deferred time only, e.g. this is the case for TAI. Such a delay of access has some practical drawbacks, but it has two important advantages: it allows a better comparison of the participating clocks when they are in different laboratories, by averaging the noise of the time comparison technique, and also a better characterization of the stability of the clocks, when long-term stability is demanded.

Timing data are time differences between clocks. Time markers from a clock may take the form of electric pulses (e.g. 1 pulse s^{-1}) or, alternatively, the phase of a

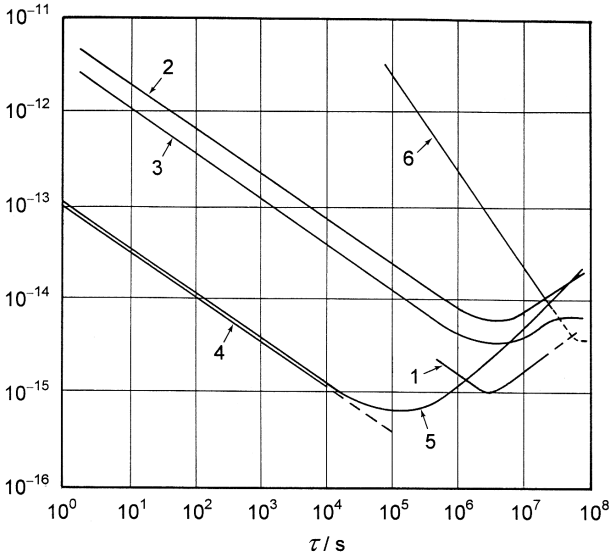

Figure 1. Relative frequency stability versus averaging duration τ for TAI (1), various atomic clocks (2–5) (2, commercial cesium clock; 3, primary clock PTB-CS1 (Braunschweig); 4, cesium fountain LPTF-FO1 (Paris); 5, commercial hydrogen maser) and the rotation of a best-case millisecond pulsar (6). Dashed parts correspond to expected or possible values.

periodic signal (e.g. 10 MHz) locked to the clock may be monitored. For clocks located at the same site, the time differences are measured by digital counters (for pulses) or heterodyne systems (for periodic signals), and each instantaneous measurement may have an uncertainty well below 1 ns. For distant clocks, time transfer techniques must be used (see below) and the typical uncertainty is of the order of a few ns for integration times of minutes to hours.

Given an ensemble of n clocks for which at some epoch t the time and frequency differences between clock i and the ensemble time TA(t) are designated by $x_i(t)$ and $y_i(t)$, respectively, then the set of n time differences $x_i(t')$ at a later time $t' = t + \delta t$ may be computed from the $n-1$ time differences measured between the clocks at time t' using an additional equation which expresses the frequency stability of the clocks as a weighted average:

$$\sum_i w_i(t')x_i(t') = \sum_i w_i(t')x_i(t) + \sum_i w_i(t')y_i(t')\,\delta t$$

where $w_i(t')$ represents the weight attributed to clock i and where the frequency difference at time t', $y_i(t')$, has to be estimated. Variations in the processes used to estimate the weights $w_i(t')$ and the frequencies $y_i(t')$ and in the choice of the time increment δt characterize the different stability algorithms. Usual features are to assume $y_i(t') = y_i(t)$ and to impose some constraints on the weights $w_i(t')$ such as a maximum weight for any given clock, whatever its apparent stability, or a null weight attributed to new clocks. Such constraints increase the reliability of the time scale at the expense of a small loss in its stability.

Construction of TAI and UTC, and some of their realizations

The first atomic clocks were built in the 1950s. When convenient techniques to compare distant clocks became available in the 1960s, it was then possible to realize an ensemble time scale. Such a task was undertaken by the Bureau International de l'Heure (BIH) in Paris and, when international agreement was deemed necessary in 1970, TAI was defined by the International Committee for Weights and Measures as 'the time reference established by the BIH on the basis of the readings of atomic clocks operating in various establishments in accordance with the definition of the second...'. In 1988 the responsibility of establishing TAI was transferred to the International Bureau for Weights and Measures (BIPM) in Sèvres (France).

As a deferred-time scale, TAI is computed each month using data provided by about 50 laboratories worldwide (figure 2). Timing data from about 220 clocks are combined using an algorithm named ALGOS, resulting in an ensemble time scale named EAL. The stability of EAL is, by its construction, optimized for an averaging time around 1 month, and this is estimated in 1999 to be about 0.6×10^{-15}. Out of the 220 participating clocks, about 120 (mostly high-performance, recently built, commercial Cs clocks) contribute to about 85% of the construction of EAL. Since EAL is free running, its scale unit (the 'EAL second') may be different from the goal set in the definition of TAI. The duration of the scale unit of EAL is measured by comparison with a number of primary frequency standards and TAI is then derived from EAL by applying a frequency correction so that the scale unit of TAI agrees with the SI second on the geoid. The relative frequency difference between EAL and TAI is at present (Spring 1999) 7.14×10^{-13} and may change slightly over time, as needed to ensure the accuracy of TAI. Over recent years, only eight primary standards have contributed occasionally or regularly to the accuracy of TAI, which is estimated to be below 0.5×10^{-14} over 1998–1999.

It has been known since the beginning of the 20th century that the EARTH'S ROTATION rate is irregular. Nevertheless, as a time based on the rotation of the Earth taking exactly 24 h (UNIVERSAL TIME UT1) had been used for decades, regulatory bodies tried in the 1960s to adapt the new atomic time to the former scale. This yielded in 1972 the definition of UTC: it differs from TAI by an integral number of seconds so that the difference between UT1 and UTC remains always smaller than 0.9 s. To ensure this, the International Earth Rotation Service in Paris issues predictions of UT1 − UTC and decides, when appropriate, to insert one leap second in UTC or alternatively to remove one second from UTC. Such operations are done at the last second of the month of June or December. From 10 s in 1972, the difference between TAI and UTC has increased to 32 s in 1999 and a leap second is inserted every 18 months on average. This is because the SI second has not been designed so that 86 400 of them match the average solar day.

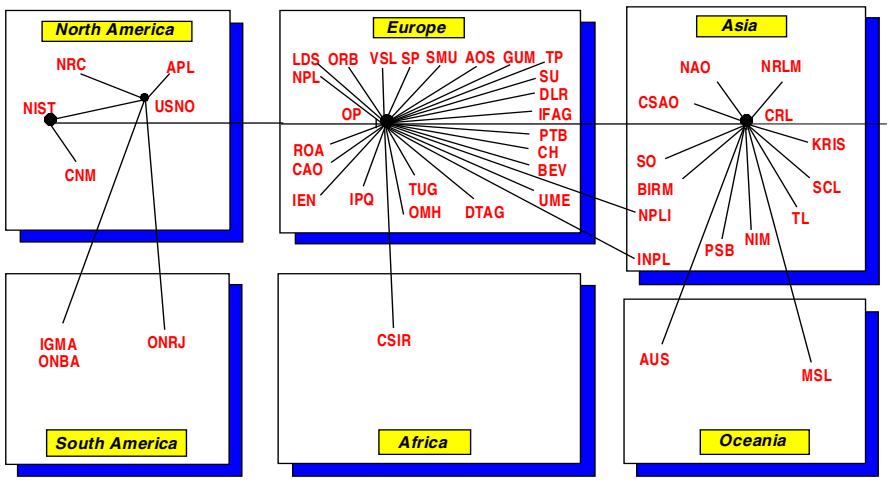

Figure 2. Schematic map of the laboratories and time links used in the computation of TAI (May 1999).

With UTC as the basis for all legal time scales, national metrology laboratories provide to their customers a real-time realization of UTC, denoted UTC(k) for laboratory k. Since UTC is not available in real time, UTC(k) may not exactly reproduce UTC, but modern clocks easily allow it to remain within ± 100 ns, a goal recommended by the CCDS in 1993. In contrast to UTC, the time scales UTC(k) must be physically realized, for example by an electrical signal at a given point, so that metrology laboratories may, in real time, drive time and frequency dissemination or comparison systems for national users. The civil time for a given country is then generally defined by adding or substracting an integral number of hours to UTC.

The leap second system, although very simple, has important drawbacks for those responsible for realizing continuous time references, e.g. for satellite systems or telecommunications. They may use TAI or generate their own time scale (such as GPS time) but, in any case, it is necessary to continue to trace the difference between this time scale and UTC. Some scientists have suggested abandoning the leap second system; there is, however, considerable inertia and such a step is unlikely to happen soon.

Clock comparison and time dissemination techniques

In the context of relativity theory, there is no *a priori* definition of simultaneity and therefore synchronization or, more generally, comparison of clocks is arbitrary. Since TAI is defined as a coordinate time, it is appropriate to define coordinate synchronization: two events are synchronous if they have the same time coordinate. In this framework, there are usually two ways to compare distant clocks: one method is to transport a portable clock from one clock to the other, properly accounting for the coordinate time accumulated during the transport (it differs from the proper time measured by the portable clock; the difference is usually called the 'relativistic corrections'); another method is to send an electromagnetic signal from one clock to the other, properly accounting for the coordinate time of propagation of the signal. Such procedures have been carried out since the development of atomic clocks. The distinction between proper and coordinate time, however, is only useful when aiming at an uncertainty below 1 μs for time comparison and below 1×10^{-12} for frequency comparison on Earth, which is what we consider in the following. At or above this uncertainty level, a number of time and frequency dissemination techniques have been and are still used, ranging from signals in the VLF (tens of kHz) or short-wave (tens of MHz) radiofrequency bands to the use of telephone lines or the world-wide web.

The clock transport technique is rather cumbersome but has been much used until the development of the GPS in the 1980s. It provided an uncertainty of some tens of nanoseconds, mainly limited by the instability of the transported clock. Although at present rarely used, an uncertainty of about a few nanoseconds is attained. Eventually, when the frequency stability of clocks reaches the order of 10^{-17}, an uncertainty of about a few picoseconds may be reached which would be a challenge for radiotransmission techniques.

All commonly used techniques for clock comparison rely on the transmission of electromagnetic signals. They can provide synchronization with an uncertainty of some nanoseconds or less within measuring times of a few minutes to a couple of hours and therefore achieve frequency comparison to within the present clock performances (10^{-14}–10^{-15}) in a matter of hours to a couple of days. The main technique uses signals from navigation satellites, such as the GPS or the Russian GLONASS, to compare the local clock with the clock on board the satellite. By differencing the measurements taken simultaneously at the two clocks ('common-view' processing) or at a whole network of stations ('geodetic-like' processing), the noise of the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

satellite clocks is eliminated and the resulting uncertainty in synchronization is of the order of a few nanoseconds or less with proper averaging. The main remaining source of uncertainty originates in the hardware delays and their variation with the environmental conditions. The other technique is two-way time transfer in which signals are sent in both directions over the transmission path. The link may be a radio signal through geostationary communication satellites or a laser pulse through dedicated equipment on board satellites or optical fibers. In all cases, a two-way technique takes advantage of the reciprocity of the path to cancel or reduce some sources of error so that the measurement uncertainty is, in principle, somewhat lower.

Future trends

Important progress has been accomplished in recent years in new techniques promising the future development of ultrastable clocks that will bring new horizons to terrestrial time scales. Two main directions are being explored for these clocks: laser cooling of atoms and ion traps. It should be noted that the 1997 Nobel prize in physics was awarded to S Chu, C Cohen-Tannoudji and W Phillips for their work on the development of methods for cooling and confining atoms using laser light. The first primary frequency standard successfully using these techniques has been the Cs fountain at the LPTF in Paris which provided a few evaluations of the SI second with uncertainties of (2–3) $\times 10^{-15}$. It is expected that an accuracy of 1×10^{-16} may be reached with such a fountain and that a fountain using rubidium atoms may be more stable. Based on a slow beam of cold atoms, similar devices operating in space in zero gravity may reach an accuracy of 1×10^{-17}. Comparing such clocks at a distance will necessitate new developments for radiotransmission or laser techniques which are envisioned for the Atomic Clock Ensemble in Space (ACES) experiment planned on board the International Space Station. It will also be necessary to reconsider the definition of TT and TAI which are limited to about 1×10^{-17} by uncertainties in the definition of the geoid.

Titan

Titan, SATURN's largest satellite, is a distant world: far away from the Sun and its close, warm TERRESTRIAL PLANETS. A fair distance from Saturn, too. Seen from Titan, at more than a million kilometers away, Saturn looks like a big yellowish ball, permanently girdled by an icy hoop. The Sun's disk is hard to see at a distance of close to one billion five hundred kilometers, more than nine times farther away than the Earth. As a consequence, our star is a hundred times dimmer there, and the temperatures prevailing on Titan drop to 70 K (−200 °C) in the atmosphere. This atmosphere is thick enough to make Titan an important but mysterious object in our solar system. Even from a near-by distance, as VOYAGER 1 found out in 1980, the dense cloud decks surrounding the small world obscure any glimpse of its surface, as on Venus.

The cameras of Voyager 1 afforded a close view of the satellite in 1980, from only 4394 km to the surface. Voyager 2 flew by Titan nine months later but at a distance a hundred times greater. The first images of the satellite that were returned in November 1980 were somewhat disappointing: Titan's visible appearance seemed unexciting—a reddish-brown ball, completely covered by a thick haze which allowed no visibility of the surface (figure 1). The most obvious feature seen by Voyager was a difference in the brightness of the two hemispheres, the northern side appearing darker than the southern. This difference is of the order of 25% at blue wavelengths, and falls to a few per cent in the ultraviolet and at red wavelengths. This north–south asymmetry is probably related to circulation in the atmosphere pushing haze from one hemisphere to the other. When Voyager 1 approached Titan, the brighter hemisphere had less haze than the darker one. Voyager also saw a dark ring above the north (winter) pole. This feature, termed the polar hood, extending from 70 to 90 degrees north latitude, is most prominent at blue and violet wavelengths, and may be associated with lack of illumination in the polar regions during the winter (since the subsolar latitude extends to 26.4°) and/or downwelling in global circulation. The altitude of vertical optical depth unity is of the order of 100 km. The asymmetry has been observed to reverse—when the HUBBLE SPACE TELESCOPE (HST) first observed Titan in 1990, a little over a quarter of a Titan year after the Voyager encounters, the northern hemisphere was found to be brighter than the south. Whereas Voyager only observed up to red wavelengths, HST has since imaged Titan in the near-infrared. At these wavelengths, the asymmetry is reversed, and indeed is somewhat stronger than in the visible. This is due to the wavelength dependence of the atmospheric brightness (bright at short wavelengths due to Rayleigh scattering, dark in the near-infrared due to methane absorption) and of the haze (presumed to be dark in blue and bright at red and longer wavelengths, by analogy with 'tholin' material generated in the laboratory). The word tholin was first used by Carl Sagan and comes from the Greek word, meaning 'muddy'.

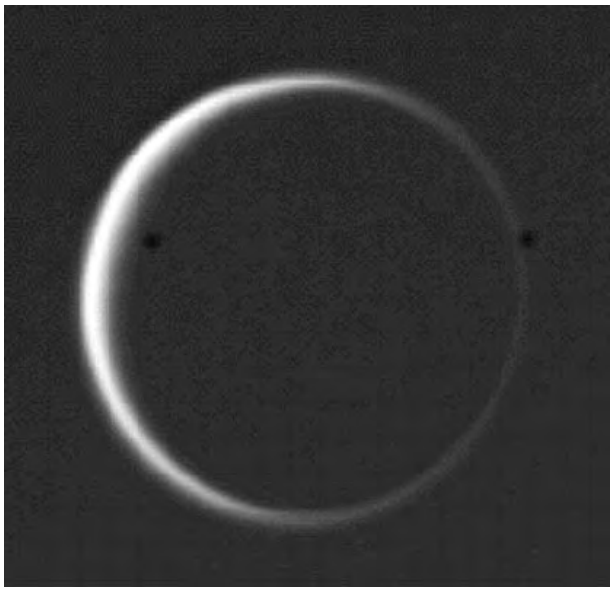

Figure 1. This view of Saturn's largest satellite was taken from a position of Voyager 2 looking almost directly back toward the Sun and the Mercury-sized body. Titan's hydrocarbon-rich nitrogen atmosphere scatters sunlight in a forward direction over the limb around the entire disk. The surface of Titan is obscured due to a deep cloud layer. The diameter of Titan is 5150 km. (Courtesy NASA/JPL).

The radio-occultation experiment aboard Voyager 1 provided a precise value of Titan's surface radius: 2575 ± 2 km, with a surface temperature of 94 ± 2 K and a pressure of about 1.45 bar. The main properties of Titan, as established at the time, are listed in table 1. The atmosphere is mainly formed of nitrogen (a property shared only by the Earth) and methane (molecular oxygen is lacking). Some 4 billion years ago, our Earth, like Titan, may have been shrouded in a thick atmosphere of nitrogen, deprived of oxygen and rich in methane. This distant object is then indeed tantalizing! Far from the Sun and its familiar small planets, this little frozen primitive Earth sails alone, lost in the middle of gaseous GIANT PLANETS and icy satellites. Where did Titan come from?

Origin and first insights

With a size half of that of the Earth's, Titan was challenged from its position as the largest satellite in our solar system by GANYMEDE, Jupiter's biggest satellite, found by Voyager to possess a few kilometers more in diameter than Saturn's champion. The latter is, however, still the ninth largest object around our star (by far bigger than the Moon and Pluto and barely bigger than Mercury), tenth by its mass (much lighter than Mercury: 140 billions of billions tons for the satellite against 330 billions of billions tons for the small planet). The satellite's mass, made of a mixture of water ice and rock (with the ice apparently containing even greater amounts of frozen, trapped and adsorbed gases

¶ Mass of Earth $= 5.98 \times 10^{24}$ kg.

than the other icy satellites, as the distance from the Sun increases), gives Titan a mean density of about 1.90.

Traveling on an almost circular prograde orbit, in the ecliptic plane, Titan takes a little under 16 days to complete its trip around Saturn, 1.2 million kilometers away, three times the Earth–Moon distance. The orbit of Titan about Saturn is significantly eccentric, with $e \approx 0.028$, which is too large to be due to perturbations by existing bodies in their present locations and may have been due to the relatively recent impact of a large body such as a comet. Titan is located in the outskirts of the Saturnian system along with Hyperion, Phoebe and Iapetus, the other 'strange' icy satellites (see SATURN: SATELLITES). But Titan is different: it has an atmosphere to boast of.

Why is Titan unique among the moons of the solar system in having a substantial atmosphere? It is perhaps not surprising that the other Saturnian moons are airless, because they are relatively small, but three of the Galilean moons of Jupiter, and Neptune's large satellite Triton, are comparable in size to Titan, while Ganymede is actually slightly larger. In contrast to the essentially airless nature of the other large satellites of the solar system, Titan has an atmosphere which is thicker than that of the much more massive planets Earth, Mars and Mercury.

In the giant planet's neighborhood, Titan is the only giant satellite, since the other seventeen known today are a hundred to a hundred million times lighter than it is. Titan therefore monopolizes more than 90% of the matter, including rings, surrounding Saturn. Its dimension and orbital parameters set constraints on the formation processes: the current consensus is that the giant planets and their satellites formed from 'sub-nebulae' much as the Sun and planets formed from the primordial solar nebula. In the outskirts of the Saturnian sub-nebula, where the temperatures were low (below 135 K) and the solar wind weaker, the gases that were trapped in the ice accreted by the satellite were not released until after the formation of Titan, becoming the satellite's earliest atmosphere. Ganymede and CALLISTO (Jupiter's satellites with similar densities to Titan, but with no atmosphere), contrary to Titan, were composed of ice that solidified at low temperatures but was later heated above 135 K in the vicinity of Jupiter, which radiated so much thermal energy during its formation that it must have glowed. At a mass three times larger that Saturn's, Jupiter generated correspondingly much more heat, so that the gas content in its satellites must have been markedly depleted through sublimation. Cometary accretion is an alternate explanation, investigated in some studies.

In the case of Titan, additional heat was generated later from the decay of short-lived radioactive elements in its rocky component. Similarly to the Earth and other terrestrial planets, this distant satellite must have formed a core of dense rocky material that became surrounded by a mantle of ice. Thus Titan recovered a secondary, outgassed atmosphere from the same general mechanism that produced the early atmospheres of Mars, Venus and Earth. Recent measurements of the isotopic ratios in Titan's atmosphere tend to favor outgassing from the interior rather than the cometary origin. In the cold and calm environment of its planet, at more than 1 billion kilometers from the Sun, Titan was able to preserve its atmosphere for more than 4.5 billion years; Mercury, the Moon, Ganymede or Callisto did not have that chance.

None of the above explains why Titan has more atmosphere than Mars or the Earth. Perhaps the atmosphere of Titan was frozen during the epoch when Mars' atmosphere, and to a lesser extent Earth's, was depleted by heavy bombardment. Alternatively, there may be a supply of the more volatile ices, such as ammonia, methane and carbon monoxide, trapped inside Titan by layers of frozen water and able to escape only slowly through cracks or 'cryovolcanoes'. It is also conceivable that Titan's atmosphere has been more efficiently replenished by incoming cometary material in relatively recent epochs, compared to the inner planets. All of these scenarios implicitly favor ammonia as the source of Titan's nitrogen atmosphere, a problem which is discussed in the next section.

The atmosphere: temperature and composition

Prior to the Voyager 1 encounter knowledge of Titan was scanty, albeit intriguing. Discovered on 25 March 1655 by the Dutch astronomer Christiaan Huygens, orbiting at a distance of about 1.2 million km from its primary, or some 20.6 Saturn radii, Titan was long known to have a substantial atmosphere: Catalan astronomer Jose Comas Solà claimed in 1908 to have observed limb darkening on Titan (that is a stronger attenuation of the light reflected from Titan's limb rather than by its center, usually associated with a thick atmosphere). To test this claim, Sir James Jeans decided in 1925 to include Titan and the biggest satellites of Jupiter in his theoretical study of escape processes in the atmospheres around solar system objects. His results showed that Titan could have kept an atmosphere, in spite of its small size and weak gravity, if low-temperature conditions, that he estimated as between 60 and 100 K, prevailed. In this case, any gas of molecular weight greater than or equal to 16 (such as ammonia, argon, neon, molecular nitrogen and methane, among those which were present in the mix of gas and dust particles that condensed to form the Solar System) would not have escaped Titan's atmosphere since the satellite's formation. In 1944, Gerald Kuiper discovered the spectral signature of methane on Titan by observing its absorption bands at 6190 Å and 7250 Å, but it remained uncertain whether it was the major atmospheric gas or a minor component mixed with another, as yet undetected but quite abundant, gas in the atmosphere.

Before the Voyager encounter, opinions were therefore divided on the principal constituent of Titan's atmosphere. One model favored methane as the main component (about 90%) of the atmosphere, and predicted surface conditions of $T = 86$ K at a pressure of 20 mbar. Another model expected that dissociation of ammonia would have produced molecular nitrogen in large quantities and held that the surface temperature and pressure would be quite high (200 K and 20 bars).

Chemical composition

Voyager 1 came to its rendezvous with Titan in November 1980. Molecular nitrogen turned out to be by far the major constituent in Titan's atmosphere, methane accounting for only a few per cent. The lightweight hydrogen gas rapidly escapes to space, because of Titan's low gravity; it is, however, being continuously generated as well, amounting to a relative abundance in the atmosphere of about 0.1%, representative of the balance achieved between its production and loss. Titan moves in and out of Saturn's magnetosphere (see SATURN: MAGNETOSPHERE INTERACTION WITH TITAN). The satellite itself bears no significant magnetic field, so that ions and electrons from Saturn can interact directly with its upper atmosphere, affecting neutral gases. As they become ionized, some of them may be swept away by the magnetic field, thus causing the loss of more gas (other than hydrogen) to space. The infrared spectrometer on board Voyager 1, IRIS, sounded the satellite's stratosphere (that is the part of the atmosphere between roughly 200 and 500 km of altitude). The infrared data taken by IRIS confirmed the presence of some simple hydrocarbons (such as methane, acetylene, ethylene and ethane) and proved the existence of some more complex ones at a few tens ppb: diacetylene (C_4H_2), methylacetylene (C_3H_4), propane (C_3H_8) and monodeuterated methane (CH_3D). Also, the signatures of some nitriles were found in the spectra: HCN, HC_3N, C_2N_2 and C_4N_2 (only in the solid phase). Finally, carbon dioxide (CO_2) was identified at 667 cm^{-1}. By comparison with laboratory spectra the abundances of these species were estimated at a few ppb. Today we have established the existence, from ground-based observations, of some other compounds in the atmosphere, including CO and CH_3CN (acetonitrile). N_2, H_2 and carbon monoxide are expected to be uniformly mixed throughout the lower atmosphere. Titan was observed again in 1997 with the Infrared Space Observatory (ISO) in the infrared range (figure 2), and from these observations more precise abundances for the atmospheric components on a global average were derived.

Methane should also be uniformly mixed globally, but since it may undergo phase changes in the troposphere, it is expected to vary with altitude. Thus, its mixing ratio (which is still poorly known) is supposed to be constant above the condensation level, below which methane may be saturated and could form clouds. Such clouds may be necessary to account for the observed opacity in the spectra between 200 and 400 cm^{-1}. The methane abundance can therefore increase with temperature down to the surface. Ultraviolet light from the Sun converts methane into more complex hydrocarbon molecules and hydrogen gas. The hydrocarbons combine with nitrogen to form nitriles. All these organics remain on Titan, eventually condensing at low altitudes. After methane, the next most abundant hydrocarbons are ethane, acetylene and propane. Unless supersaturation conditions prevail, each of these organics and the less abundant ones must condense at some level in the lower stratosphere and precipitate out, effectively reducing its gas phase abundance to smaller amounts below this level.

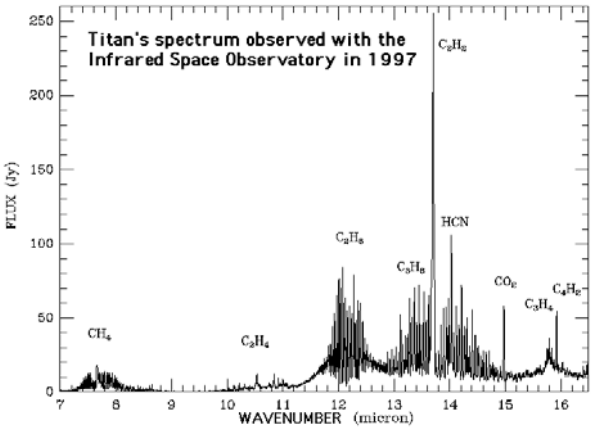

Figure 2. Spectrum of Titan, showing the signatures of the atmospheric components (hydrocarbons, nitriles and CO_2), acquired with ISO Short Wavelength Spectrometer in January 1997 in the grating mode, with a resolving power between 1500 and 3000.

Latitudinal variations in the atmosphere were observed for some of the least abundant molecules, with an obvious enhancement of HC_3N and C_2N_2, as well as of some hydrocarbons, at high northern latitudes, and seasonal effects were suggested as the origin of these variations.

Carbon monoxide (CO) and carbon dioxide (CO_2) along with water are currently the only oxygen compounds found in Titan's atmosphere. CO was first detected in 1983 from ground-based observations in the near-infrared, with a tropospheric abundance of $\sim 6 \times 10^{-5}$, in fair agreement with the prediction of the photochemical models in existence. CO_2 was identified in the Voyager 1/IRIS spectra from the emission feature around 667 cm^{-1}. Also observed with ISO (figure 2), the CO_2 average mole fraction in Titan's atmosphere above the 110 mbar level is found to be the same as that found by Voyager, about 10 ppb (assuming a vertical CO_2 profile constant with height), while the associated mixing ratio of stratospheric CO, measured from ground-based microwave and millimeter observations, is on the order of (1–5) $\times 10^{-5}$.

The recent detection of water in Titan's atmosphere with the ISO was an important result because it explains the presence of CO and, especially, of CO_2. The water vapor abundance is on the order of a few tens of a ppb at an altitude of 400 km. CO is produced by reactions of OH with CH_2 or CH_3, if the latter is present at sufficiently high levels in the thermosphere. OH also destroys CO, at lower levels near 500 km, with subsequent re-formation of CO_2. At equilibrium, the photochemical lifetime of CO is very long (comparable to the age of Titan itself), and as a consequence, the production of CO_2 from H_2O is in fact independent of the amounts of CO present in the stratosphere. The inferred value for the water influx on Titan is comparable with recent estimates from water detection on Saturn by ISO (5×10^6 cm^{-2} s^{-1}). Further progress on the whole question of oxidized molecules in Titan's atmosphere awaits new and more precise values for their abundances, which will probably come from Cassini/Huygens measurements in 2004.

The ultimate sink of the oxygen, coming in at the top of the atmosphere as H_2O, is at the surface of Titan, where it precipitates out as frozen CO_2. The lower atmosphere is, of course, in contact with the ground. The upper part or crust of the solid body of Titan is expected to consist mostly of water ice, although whether this is in direct contact with the lower atmosphere will depend on the nature and thickness of any coating of other condensates (solid CO_2, for example, or the hydrocarbon-based liquids and solids discussed elsewhere). If there is good contact, the troposphere could be saturated with water, albeit at temperatures so low that this corresponds to a very low mixing ratio (which explains why the icy rings and satellites of Saturn have survived for billions of years without vaporizing). The relatively warm upper atmosphere, which could hold proportionally more water, is probably prevented from doing so (unless there is an external source) because of the cold-trap formed by the tropopause. It is for the same reason that the stratosphere of the Earth is very dry. In other words, the water ice on the surface does not participate in the atmospheric photochemistry. If Titan was set closer to the Sun, warmer surface temperatures would cause the water to sublimate and move into the atmosphere. As a result, the oxygen provided in this way would rapidly combine with the methane and other hydrocarbons and form large amounts of carbon dioxide, similar to Venus and Mars. The character of Titan's atmosphere would radically change, but not necessarily towards something closer to the Earth.

Origins of the atmosphere

It is intriguing that Titan's primary atmospheric component is the same as the Earth's. What is the origin of the nitrogen in Titan's atmosphere? In particular, is it derived from a source containing molecular nitrogen or was it produced by chemical processing of ammonia (or some other process)?

There seem to be four possible scenarios. The first, and least probable, is that direct capture of N_2 from the solar or proto-Saturnian nebula took place. Even if this did occur, it is believed that Titan's primitive atmosphere, like that of the Earth, was lost long ago as part of the formation process, and replaced by a 'secondary' atmosphere which outgassed from the interior. This, however, could have involved devolatilization of nitrogen-containing ices condensed from the nebula.

It seems more likely that the primordial cloud contained nitrogen primarily as the hydride, ammonia, which is also far less volatile and therefore easier to accrete as early Titan cooled. If we imagine, as our third possible scenario, a variant of this in which Titan's atmosphere formed from the same mix of gases which are present on Saturn, the heavy components, primarily ammonia and methane, would be retained while

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

hydrogen and helium were lost (on Titan, but not on Saturn). Photolysis would eventually produce N_2 from the NH_3 and higher hydrocarbons—including those which condense as aerosols—from the CH_4, so we could end up with the atmosphere forming much as we see it today. There is no first-order difference whether the gases came from the interior, from ices frozen on the surface, or directly from the nebula. Titan should then have the same isotopic composition as Saturn, for the ratio of deuterium to hydrogen in particular, possibly somewhat modified after accretion by the impact of volatile-rich comets, or by other processes such as possible impacts from debris resulting from the apparent damage to HYPERION.

Deuterium (D), the first isotope of hydrogen, has a neutron in addition to the proton of the common hydrogen atom. Deuterium is therefore twice as heavy as hydrogen and has, accordingly, a different physical behavior. By studying its abundance today, we may learn something of the chemical processes involved in the atmosphere of a planet in the past. On Titan, most of the hydrocarbon is in the form of methane (CH_4). Recent measurements of the D/H ratio on Titan with ISO (7.5×10^{-5} derived from the CH_3D isotope of methane) are lower by a factor of 4 or more than those measured in water in the comets Halley, Hyakutake and Hale-Bopp, and therefore tend to rule out a pure cometary source for the atmosphere of Titan. It seems thereby that the Titan D/H ratio is consistent with the formation of the atmosphere by outgassing from the interior of the satellite. On the other hand, D/H on Titan is somewhat larger than the value for Saturn (representative of the protosolar nebula), where D/H is believed to be around 2.5×10^{-5}. This suggests that Titan's present-day atmosphere has been somewhat enriched in deuterium since it formed from the proto-Saturnian nebula, by cometary material or in some other way: some scenarios suggest that methane in the sub-nebula of Saturn could have been enriched in deuterium, relative to that in molecular hydrogen, prior to the formation of the satellites by a factor of about 1.4. In addition, it is possible that some fractionation, mainly due to the photodissociation of methane, could have occurred during Titan's history.

The basic question of whether the nitrogen arrived as N_2 or NH_3 could find an answer in measurements of the Ar/N_2 ratio in the present-day atmosphere. Because molecular nitrogen and argon have similar vapor pressures, a large argon abundance suggests N_2 while a small one favors NH_3 as the source of the present-day nitrogen. Thus knowing whether argon is abundant or not on Titan, would enable us to choose between various formation models of the satellite. Unfortunately, none of the noble gases has yet been detected on Titan. The presence of argon has been deduced only indirectly—the value of the mean molecular weight of Titan's atmosphere is uncertain enough to allow for up to 7% or none at all, in which case the nitrogen fraction would increase, and it would seem more likely again that nitrogen arrived as ammonia on Titan.

Aerosols

Titan's atmosphere is known to contain particles (aerosols) in addition to gas. As Voyager 2 flew in the satellite's shadow, Titan's atmosphere, scattering solar light, formed a bright crescent almost entirely circling the dark disk (figure 1). The particulate haze around Titan extends to an altitude of about 200 km, with a detached and much more tenuous layer about 100 km higher. In the Voyager images the two layers appear blended. The haze on Titan is not very dense; it is, however, deep enough to completely hide the surface in the visible.

It is established today that the aerosols in Titan's atmosphere are condensed forms of the gases mentioned above. Condensed ethane, for instance, falling through Titan's atmosphere, may form clouds or haze, or even possibly near-surface mist. Theoretical considerations suggest that thin, patchy clouds of methane crystals and a photochemical fog of more complex condensates might both be present, the latter arising as a result of methane photolysis at ultraviolet wavelengths following which the fragments combine to produce polymers which condense to form oily droplets at Titan's temperatures. The brownish tarry organic sludge produced by photochemistry in Titan's atmosphere condenses near the tropopause. Although the exact nature of these compounds is not known, their size, from Voyager observations, seems to be on the order of 1 micron in diameter. The aerosols are then too heavy to remain suspended in the atmosphere: they must eventually fall on the surface, where they may be exposed or hidden in subsurface reservoirs. Some of these molecules, like hydrogen cyanide (HCN), are pre-biotic, similar to those produced in experiments on the origin of life on Earth. Existing models designate these same products of methane as the precursors of organic molecules and hence amino acids and, ultimately, the first living cells in primitive Earth's warm oceans. However, more work is needed to show how well the products of laboratory simulations ('tholins') match the aerosols in Titan's atmosphere.

Temperature

By analogy with the Earth, Titan's atmosphere is subdivided into layers defined by the temperature variations with height (or pressure, through the hydrostatic law). On both Titan and the Earth, the mean temperature profile is characterized by two temperature inversions (locations above which the temperature increases with altitude, while the opposite takes place beneath). Much of the electromagnetic radiation emitted by the Sun and reaching a planet is at wavelengths in or near the visible part of the spectrum. The aerosol layers scatter the photons and reflect a portion of the radiation back to space, some of it is absorbed by the haze and clouds, if any are present, and the atmospheric gases. The rest of the energy, about 10% on Titan, reaches the ground where it is absorbed.

However, the analogy between the two atmospheres shouldn't be carried too far: for one thing, the vertical extent of each region is different, with Titan's atmosphere generally being more extensive than the Earth's. In fact,

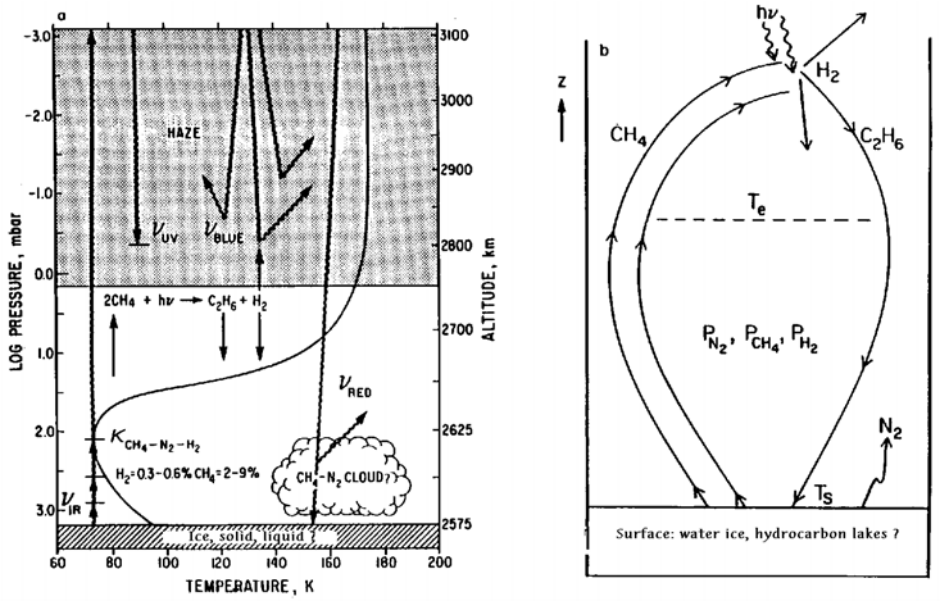

Figure 3. Schematic of Titan's surface–atmosphere system. (Figure adapted from Thompson and Sagan (1984).)

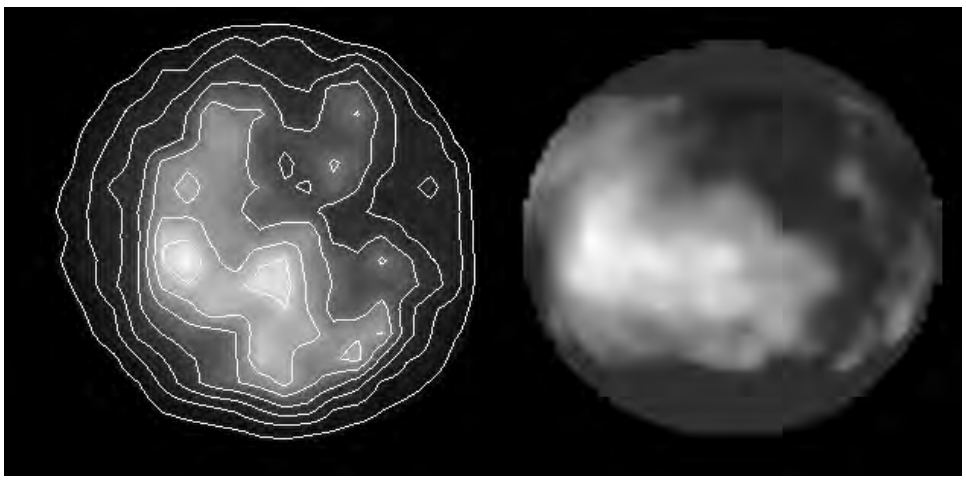

Figure 4. Images of Titan's surface at 0.94 μm (right) and 2 μm (left), obtained with the HST and ADONIS/ESO respectively in 1994. Note the large bright equatorial region which is located on the leading hemisphere. (Courtesy of M Combes and P Smith.)

the extent of Titan's atmosphere is comparable to the radius of the solid body (2575 km), while that of the Earth's is sometimes likened to the skin on a grape. The Earth's tropopause (location of the lower temperature inversion) varies in height over about 6 km with latitude, being highest (around 16 km) in the tropics where solar heating is greatest, but it is generally quite a sharp feature in the temperature profile everywhere (see EARTH'S ATMOSPHERE). On Titan the troposphere (lower part of the atmosphere) extends from the surface up to about 40 km, while the stratosphere (middle atmosphere) reaches up to altitudes of 500 km.

Titan's temperature with height was determined near the equator through a combination of data from the radio occultation experiment and the infrared spectrometer on the Voyager spacecraft. The results show that Titan affords a GREENHOUSE EFFECT in its troposphere (the lowest 40 km). This phenomenon, similarly as on Earth, causes the temperature to increase from a minimum (~71 K) at the tropopause (the upper boundary of the troposphere at 40 km) and down to the surface (94 K). This is a consequence of a region of heating in the middle atmosphere of both Titan and the Earth, due to the Earth's stratospheric ozone layer in one case and Titan's deep aerosol layer in the other. Both of these absorb solar energy and heat the troposphere, producing a local

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

temperature maximum at the surface (figure 3). The surface temperature is then about 12 degrees higher than the effective temperature of the planet. The upper boundary of the troposphere, the tropopause, is the level where the minimum temperature is registered and the overlying atmosphere is of such a low density that a substantial amount of radiative cooling to space can occur in the thermal infrared region of the spectrum. At the tropopause, an inversion occurs and the temperature increases with height, peaking at about 180 K at around 400 km of altitude. This turnaround of the temperature is primarily due to the ultraviolet sunlight entering Titan's upper atmosphere. Its absorption contributes to the photochemical processes described below.

Little is known with certainty about Titan's troposphere. It would seem that it is different from the Earth's. While on Earth the troposphere is dominated by convection, on Titan the observed lapse rate is stable against dry convection and there is no real indication of moist convection. If radiative equilibrium prevails, the presence of a greenhouse effect is, however, a puzzle. There may still be a small convective region in the deepest few kilometers of Titan's thick atmosphere to explain how the energy deposited at the surface can escape to an optically thin level.

The gases existing in Titan's atmosphere condense at the tropopause temperature, with the exception of hydrogen, carbon monoxide and diacetylene. These condensates form bigger and bigger aggregates in the lower part of the atmosphere and give rise to haze and possibly clouds. The end-products, possibly polymers, are finally deposited on the surface.

Furthermore, there are seasonal variations on Titan, causing the atmosphere to change its compositional and thermal structure as the moon follows Saturn on its orbit around the Sun, approaching our star at 1.35 billion km and recoiling to 1.5 billion km away. As the four seasons follow one another, each lasting about 7.5 years, the temperature on Titan could well vary by 20 degrees or more. Meteorological phenomena, such as hydrocarbon rain or snow, might then well occur on this satellite, shaping a curious landscape.

The surface

Titan is the last object in our solar system whose surface remains largely unknown to us. The surface pressure on Titan is strangely high for a rather small world: 1.5 bar, versus 1 bar of pressure on the Earth's surface. The temperature, with so little solar flux reaching the ground, is dreadfully low: about $-180\,^{\circ}$C. It is not easy then to imagine the real landscape hidden under the thick Titan clouds. On Earth, at such temperatures, everything would be frozen. On Titan, however, where oxygen does not exist in a free state and where water is necessarily trapped in the form of ice on or underneath the surface (similarly to EUROPA), it is perhaps methane, ethane and nitrogen that can play the part of active liquids. At the pressures and temperatures prevailing on Titan's surface, these three gases, so difficult to maintain in liquid form on Earth, are close to their condensation conditions, where they can coexist in all three forms: solid, liquid and gas.

Figure 5. This artist's rendering depicts the NASA Cassini spacecraft in orbit around ringed Saturn (lower right background). At the lower left, the European Space Agency's Huygens probe descends to the surface of Saturn's moon Titan (in foreground). Cassini was launched on a Titan IV rocket in October 1997, with Saturn arrival in June 2004. (Courtesy NASA/JPL.)

Real observational data on the surface of the satellite are scarce, but not totally non-existent. On the one hand, nothing is visible in the ultraviolet range either from the ground or from space. On the other hand though, radar sounding, spectra and images taken in the infrared and photometric measurements never fail to supply fuel for discussions and speculations. Also, some theoretical models exist constrained by known physical conditions such as mass, density, chemical composition and temperature, vapor pressure, etc. As an example, condensed ethane (the main by-product of methane) can be found in liquid form on Titan's surface. It was thus first suggested that Titan's surface could be entirely covered with ethane–methane oceans.

Since 1994, however, observations from space (with the Hubble Space Telescope), and from the ground (using the new techniques of ADAPTIVE OPTICS in order to compensate for the atmospheric turbulence), have managed to pierce through Titan's clouds by aiming at specific frequencies in the near-infrared range, where atmospheric 'windows' (or regions where the methane absorption is weak) allow us to sound the lower part of the atmosphere and the surface of the satellite. From these images, a new picture of Titan's surface emerged: dark and bright areas cover the surface of the satellite (figure 4). These images confirm spectroscopic observations from 1994, which indicated a brighter leading hemisphere and a much darker trailing side on Titan. Thus, Titan's surface is certainly inhomogeneous, and cannot be covered with uniform hydrocarbon oceans. The observations allow though for a number of options, such as local

hydrocarbon lakes and rocks to exist on the surface and for patchy methane clouds to form in the lower troposphere. The most recent and somewhat speculative model of Titan's surface produces an exciting image: Titan would be covered mainly with water ice and organic deposits, but the morphology would allow for frosty relief, perhaps mountains or craters covered with methane snow, their shores beaten by the waves produced in the vast hydrocarbon lakes ....

When the ambitious scientific CASSINI MISSION/Huygens (figure 5), launched successfully from Cape Canaveral on 15 October 1997, reaches this distant world, in 2004, astronomers will discover the true nature of this little hibernating moon, and of its ground in particular, from where its planet Saturn is barely visible. While the orbiter, Cassini, developed by NASA, performs its four-year thorough investigation of the Saturnian system, with numerous flybys scheduled for Titan, the probe Huygens, constructed by the European Space Agency, will descend into Titan's atmosphere and should hopefully land on its surface, giving us access to the thrilling results of what might be the last big space mission for years to come. In the meantime, one can always dream of the science fiction landscapes which characterize this frozen, dark world and which will then be revealed to us.

Titania

A mid-sized satellite of Uranus, discovered by William Herschel in 1787. Its diameter is 1580 km and it orbits at a distance of 191 000 km. The part of Titania imaged by Voyager 2 consists of a large plain covered with small craters, crossed by large canyons where the crust has faulted. The most extensive of these is the Messina Chasmata system, with an overall length of nearly 1500 km and 100 km across at its widest point. The 326 km diameter Gertrude is the only large crater; the general lack of large craters may indicate that Titania has been resurfaced in the past. The surface resembles that of Ariel, another Uranian satellite, and the processes that operated there are probably those that have shaped Titania's surface.

Titius, Johann Daniel (1729–96)

German astronomer, born in Konitz, Germany (now Poland), professor of physics at Wittenberg, built the first lightning conductor. He interpolated into the translation he had prepared of a book by the naturalist Charles Bonnet the relation between the distances of the planets that he had discovered. The planets, Titius pointed out, were at distances from the Sun that were in proportion to the sequence 4, 4 + 3, 4 + 6, 4 + 12, 4 + 48, 4 + 96. Bonnet had commented in respect of the missing number in the sequence of 4 + 24 'But should the Lord Architect have left this space empty?' and the asteroids were later found to correspond to it. Titius' discovery was popularized by BODE and is known as *Bode's law* or, only sometimes, as the *Titius–Bode law*.

Tombaugh, Clyde William (1906–97)

Born near Streator, IL, became interested in astronomy as a boy and, on the basis of some observations which he sent to the Lowell Observatory, was hired as an astronomer there to search for 'Planet X' beyond Neptune. Photographing 65% of the sky, he discovered several star clusters, two comets, more than a hundred asteroids, dozens of clusters of galaxies—and the planet Pluto. He worked on the captured V-2 rockets at White Sands, and became professor at New Mexico State University, where he confirmed the rotation period of Mercury on its axis, determined the vortex nature of Jupiter's great red spot, and looked for small, natural Earth satellites.

Tompion, Thomas (*c.* 1639–1713)

Clockmaker, born in Northill, Bedfordshire, England, made the clocks for the Royal Observatory, Greenwich, the first clocks to keep Greenwich Mean Time and demonstrate the uniformity of rotation of the Earth. The clocks had 4 m pendulums, with a 2 s swing, and were the reason why the observing room (the Octagon Room at Flamsteed House) was designed by CHRISTOPHER WREN with such high ceilings. Tompion kept the cases locked and would not let JOHN FLAMSTEED have the key. After Flamsteed's death, the clocks were re-made with conventional meter-long pendulums and sold for domestic purposes, but one was recently restored to its original location.

Topological Defects in Cosmology

In modern theories of particle physics, an important consequence of phase transitions in the early universe is the formation of topological defects, that is domain walls, cosmic strings, monopoles or textures. These defects are essentially trapped fossils of a hot dense early phase of matter in the universe. They have well-known analogues in the low-temperature laboratory and in other contexts, including domains in a ferromagnet and vortices in superfluids and superconductors.

The potential existence of topological defects has both troubled and fascinated cosmologists since the late 1970s. On the one hand, domain walls and monopoles are incompatible with the standard hot BIG BANG cosmology because they would dominate the energy density of the universe today. Such considerations constrain the range of viable fundamental theories. On the other hand, cosmic strings and some other defect types are cosmologically benign and may have had an important role in the history of the universe. Because cosmic defects can be supermassive, a great deal of interest has focused on the idea that they were the primordial seeds for large-scale structure formation. This idea is now under observational pressure, but a contributory role in GALAXY FORMATION cannot be excluded. Defects can also form at lower energy scales and, in particular, those appearing at the electroweak phase transition are believed to have influenced the matter–antimatter asymmetry of the universe. In addition, cosmic defects have been invoked to explain the origin of missing DARK MATTER, ultra-high-energy COSMIC RAYS and a number of other outstanding cosmological enigmas. The place of topological defects in fundamental theory is secure, but their corresponding role in cosmology remains to be fully understood and empirically tested.

In what follows, the sections on 'Domain walls and the Kibble mechanism', 'Defect classification', 'Gravitational effects on cosmic strings' and 'Quantitative string networks' are more technical and may be omitted on first reading. These sections are indicated between ◇ and ⧫.

The origin of defects

Descartes' theory of vortices, in which the planets were swept around the Sun in a giant whirlpool, was probably the first proposed role for topological defects in cosmology. This vortex theory may have been swept aside by Newton, but defects cannot be eliminated from particle physics models which unify the forces of nature. The basic notion is that some large continuous group G (a Lie group) with many symmetries incorporates as subgroups those which describe electromagnetism and the strong and weak nuclear forces. At high temperatures, the particle interactions are unified in this large group G, so as the universe cools it undergoes a cascade of phase transitions at which the symmetries break and the forces of nature begin to differentiate, such as, $G \longrightarrow SU(3) \times SU(2) \times U(1) \longrightarrow SU(3) \times U(1)$ (see UNIVERSE: THERMAL HISTORY). At each stage of the symmetry breaking, at least one topological defect species must inevitably emerge, although which actual species does appear and for how long depends on the exact nature of the symmetry breaking. For example, at the first stage when the group G is broken, magnetic monopoles are formed. A monopole is a point-like object with a magnetic charge which is associated with the unbroken circular $U(1)$ symmetry of electromagnetism. GRAND UNIFIED THEORIES (GUTs) can be very large and may involve several intermediate symmetry breaking transitions, so a wide variety of cosmic defects can be created.

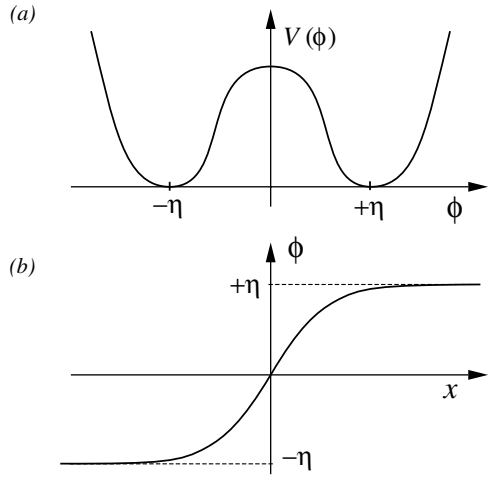

Figure 1. (*a*) Double-well potential $V(\phi)$ which breaks a discrete Z_2 reflection symmetry and has two minima at $\phi = \pm\eta$. (*b*) A field configuration in real space which interpolates between these two minima has a localized energy density corresponding to a domain wall.

◇ *Domain walls and the Kibble mechanism*

These points can be illustrated by considering the simplest case. Domain walls form when a discrete symmetry is broken as in the double-well potential $V(\phi)$ shown in figure 1. In this model, a real scalar field ϕ (or order parameter) takes particular values at every point in space. These values will, if possible, minimize the potential energy by being either at $\phi = -\eta$ or at $\phi = +\eta$, that is in one of the two minima (or vacua) of $V(\phi)$. However, if the field ϕ at $x = -\infty$ is at $\phi = -\eta$ while at $x = +\infty$ it is at $\phi = +\eta$, then ϕ must smoothly interpolate between these two minima as illustrated in figure 1. In doing so the configuration will rise up over the top of the potential $V(\phi)$ at $\phi = 0$ and so there will be a localized region of potential and gradient energies in the field ϕ. In three dimensions, this will be a two-dimensional domain wall separating regions in the two different possible vacua.

Domain walls inevitably form at any phase transition when a discrete symmetry breaks. This is simply due to causality and is known as the Kibble mechanism. At temperatures above the phase transition $T > T_c$ the

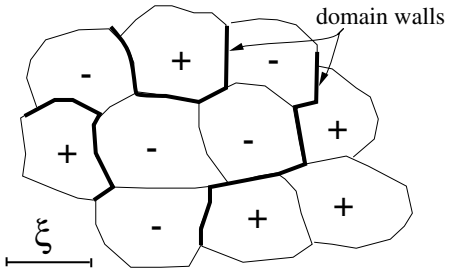

Figure 2. Topological defect formation at symmetry-breaking phase transitions—the Kibble mechanism: domain walls form between uncorrelated regions which fall into opposite sides of the double-well potential.

potential $V(\phi)$ has a minimum at the symmetric value $\phi = 0$; however, below the transition $T < T_c$ the field must randomly choose between the different discrete minimum energy states at $\phi = \pm\eta$. Regions with a volume associated with the correlation length of the field will take one random orientation or the other. However, by causality correlated regions are smaller than the horizon, so many domain walls must interpolate between the large number of regions which are necessarily misaligned. This formation process is illustrated in figure 2.

Defect classification

The classification of topological defects which form at symmetry-breaking phase transitions is most succinctly achieved using homotopy theory, but a simpler summary will suffice here. For a specific symmetry breaking scheme $G \to H$ in which the group G is broken to a subgroup H, then (i) domain walls form when G contains a discrete symmetry which is broken (e.g. $Z_2 \to I$ as above), (ii) cosmic strings form either if the unbroken subgroup H contains a discrete symmetry or if a $U(1)$ symmetry is broken (e.g. $U(1) \to I$, as in a superconductor), (iii) monopoles form when a $U(1)$ symmetry appears (e.g. $G \to SU(3) \times U(1)$ as in GUT) and (iv) textures appear when a non-Abelian group or subgroup of G is completely broken (e.g. $SU(2) \to I$ as in the electroweak phase transition). ♦

Properties of cosmic defects

The energy scale η at which the defect-forming phase transition occurs determines the key properties of a topological defect. A domain wall has a width $\delta \sim \eta^{-1}$ and a surface energy density $\sigma \sim \eta^3$ (in natural units $\hbar = c = k_B = 1$). The wall tension in the two tangential directions is equal to the surface density σ, so curved regions contract, oscillate and collide at relativistic velocities.

A cosmic string is a line-like topological defect associated with a trapped winding around a circle as illustrated in figure 3(*a*). The width of the cosmic string is $\delta \sim \eta^{-1}$ and its linear energy density is $\mu \sim \eta^2$. The string has a large tension equal to its linear energy density, so a string will oscillate relativistically. String intersections result in reconnection or the 'exchange of partners' which can lead to the break-up of a long string network into small loops. These loops have periodic trajectories and they decay by emitting gravitational radiation because they have a significant quadrupole moment.

In string models, $G\mu$ (or equivalently η^2) is the

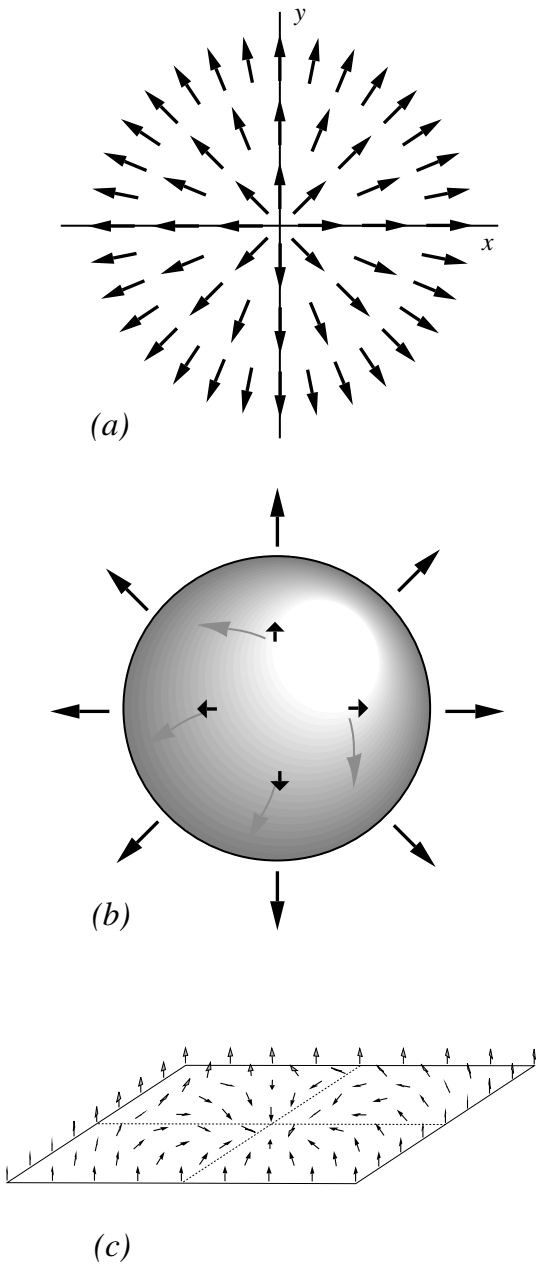

Figure 3. (*a*) Field configuration for a vortex string, corresponding to a complete winding of a complex scalar field around a unit circle (transverse section). (*b*) The 'hedgehog' configuration depicting the fields emanating from a magnetic monopole. (*c*) Two-dimensional texture configuration in which the field never becomes singular.

key dimensionless parameter which determines the magnitude of string gravity, that is

$$G\mu \sim \left(\frac{\eta}{m_{\rm pl}}\right)^2$$

where $m_{\rm pl}$ is the Planck mass ($G = m_{\rm pl}^{-2}$). For GUT-scale strings with $\eta \sim 10^{16}$ GeV we are in a linearized gravity regime with $G\mu \sim 10^{-6}$. However, this corresponds to the enormous energy per unit length of $\mu \sim 10^{22}$ g cm^{-1}, that is, a 10 km length of cosmic string weighs as much as the Earth itself. This gives an indication of their potential cosmological role as seeds for structure formation.

In addition, strings can act like superconducting wires, if they possess trapped states of charged particles which propagate along the string. The phenomenon is a fairly natural consequence of many realistic symmetry-breaking hierarchies. Unlike ordinary cosmic strings which only act gravitationally, superconducting strings can have directly observable electromagnetic effects.

Magnetic monopoles are point-like objects with a radial magnetic field, as in the 'hedgehog' configuration shown in figure 3(*b*). The magnitude of this field is $B = 1/er^2$ and the overall magnetic flux is $\Phi_B = 4\pi/e$, where e is the electromagnetic gauge coupling. The mass of the monopole is typically $m \sim 4\pi\eta/e$, which for GUT scales can be as high as $m \sim 10^{18}$ GeV (that is, up to $m \sim 1\ \mu$g).

It is also possible to envisage a 'global' monopole without electromagnetic gauge fields. In this case, the scalar fields form a similar 'hedgehog' configuration but the gradient energies at large distances are not cancelled by the gauge fields. The global monopole energy is consequently linearly divergent with $m \sim 4\pi\eta^2 R$, where R is a cutoff set by the nearest antimonopole or the field correlation length. Global monopole–antimonopole pairs are strongly confined and will approach relativistically and rapidly annihilate, unlike their weakly interacting magnetic counterparts.

Textures are non-singular amorphous defects which form when non-Abelian symmetries are completely broken. A two-dimensional texture configuration is shown in figure 3(*c*). Like monopoles, they can be either local or global. For a local texture configuration, the scalar and gauge fields can be aligned such the texture has zero energy and it can be essentially 'gauged away'. Around the time of the texture-forming phase transition, however, the texture field alignments are imperfect and transitory topological effects can have important consequences. Transitions between texture states, known as sphalerons, can occur at these near-critical temperatures or, later, by quantum mechanical tunnelling. Such sphalerons in the standard electroweak model cause baryon number violation which may have influenced the matter–antimatter asymmetry of the universe.

In contrast, global textures have no gauge fields to cancel the effects of their long-range scalar fields. However, global textures are susceptible to a shrinking instability, so they collapse relativistically to a point.

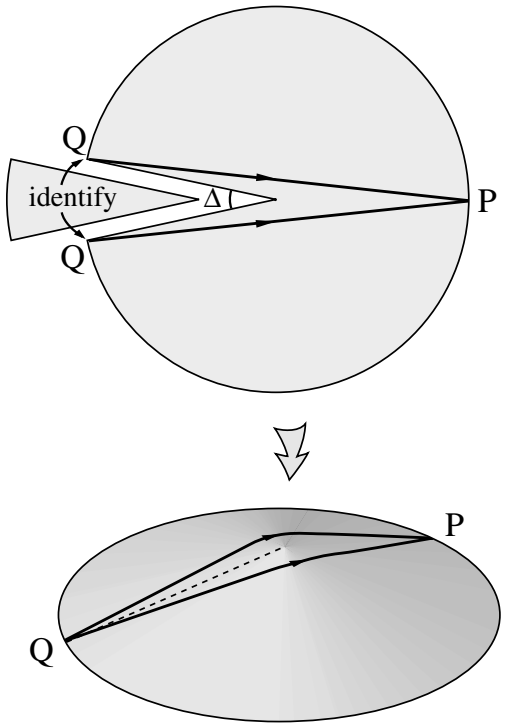

Figure 4. The conical spacetime about a cosmic string is constructed by removing a wedge of angular size Δ and identifying along the edges. Gravitational lensing by the cosmic string is also shown with the observer at P seeing a double image of the source at Q.

At this stage the configuration becomes singular and topologically unwinds; the global texture disappears in a burst of Goldstone boson radiation.

◇ *Gravitational effects of cosmic strings*

A straight string exerts no Newtonian gravitational force because the effect of its energy density is cancelled by the negative pressure of its tension. The SPACETIME locally appears to be flat but, in fact, the string induces a global distortion. Spatial sections transverse to the string are conical; to describe the space, a wedge must be removed and the remaining edges identified as illustrated in figure 4. The angular size of this wedge, known as the deficit angle, is given by

$$\Delta = 8\pi G\mu. \qquad (1)$$

Gravitational lensing by strings. This conical spacetime has a number of observational consequences including the formation of double images behind a string. Imagine a source such as a quasar located at Q in figure 4, a distance ℓ from the observer at P, who is in turn a distance d from the string. Provided that the string and source are sufficiently aligned, there are two paths by which light can reach the observer who will see two identical lensed images with an

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

angular separation

$$\delta\varphi = 8\phi G\mu\ell(d+\ell)\sin\tilde{\theta}$$

where $\tilde{\theta}$ is the angle between PQ and the string and we have assumed $G\mu \ll 1$. For a GUT-scale string with $G\mu \sim 10^{-6}$, this corresponds to a separation of a few arcseconds. The probability of a double image for a source at redshift $z \sim 1$ to be lensed by a cosmic string network is about $P \sim 100G\mu$. Despite the increasing density of strings at higher redshift, this lensing probability only grows logarithmically.

Wake formation with cosmic strings. A moving cosmic string can disturb a homogeneous matter background and induce density fluctuations. Consider two test matter particles moving along parallel trajectories with velocity v_s on either side of the string. When the line drawn between the particles crosses the string, they will both begin to move towards each other with a transverse velocity,

$$u_\perp = v_s\Delta = 4\pi G\mu v_s. \qquad (2)$$

In an exactly analogous manner, if a string moves through a static homogeneous matter background then matter particles on opposite sides will begin to move together eventually colliding in a wake or pancake-like region. Subsequently, matter will continue to accrete onto this planar overdensity. ♦

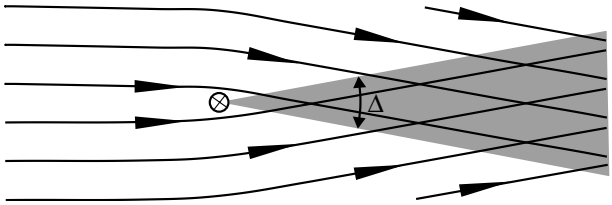

Figure 5. Wake formation induced by a cosmic string. Matter flow lines are shown in the rest frame of the string, with the density doubled in the shaded region.

Cosmological evolution

Topological defects can only be cosmologically non-pathological if their evolution is scale invariant throughout the history of the universe. In this case, the defect network approaches a 'scaling' regime in which the average number of defects in each horizon volume remains constant and they contribute a fixed fraction of the total energy density of the universe, typically of order $\sim 100G\eta^2$. For GUT-scale defects with $G\eta^2 \sim 10^{-6}$, this corresponds to a density perturbation of about the correct magnitude to seed galaxy formation.

When cosmic strings are created at a phase transition they form a network of Brownian random walks with a characteristic lengthscale ξ given by the field correlation length at that time ($\xi < H^{-1}$). Some of the strings return to their starting point to form closed loops, but the vast majority are 'infinite' (about 85%), stretching across the horizon volume and continuing on indefinitely. After a period of damped evolution, the strings begin to oscillate relativistically and ξ grows until it 'scales' as a fixed fraction of the horizon size, that is

$$\xi(t) = \gamma t$$

with $\gamma \approx \mathcal{O}(1)$. Basically, the network 'chops' itself up into small loops as fast as is allowed by causality. These loops, in turn, decay into a relatively harmless background of gravitational waves or other radiation. The energy density of a Brownian network of infinite strings is given by

$$\rho_\infty = \frac{\mu\xi}{\xi^3} = \zeta\frac{\mu}{t^2} \qquad \text{with } \zeta = \gamma^{-2}.$$

Note that like the background density in an expanding universe, the string density ρ_∞ scales as t^{-2}. Numerical simulations indicate that there are always about 40 strings per horizon volume at any time, with an example of a network shown in figure 5. However, their relative contribution to the background density changes across the matter–radiation transition with $\zeta = 13\ (\pm 3)$ during the radiation era dropping slowly to $\zeta = 4\ (\pm 2)$ in the matter era.

The requirement of scale invariance reveals immediately why both domain walls and magnetic monopoles are incompatible with the standard cosmology. Even if the 'scaling' regime only had one domain wall stretching across each horizon volume, then their energy density would be $\rho_{\rm DW} \sim \sigma t^2/t^3 \propto t^{-1}$. Thus domain walls would rapidly come to dominate over the background energy density unless their surface density σ was very small, that is the very low symmetry-breaking scale $\eta < 100$ MeV. A more stringent constraint arises from the COSMIC MICROWAVE BACKGROUND, $\eta < 1$ MeV, because a domain wall will disturb large-angle isotropy.

Magnetic monopoles are a generic prediction of GUTs, but they redshift like massive particles and so their energy density scales as $\rho_{\rm M} \propto t^{-3/2}$ during the radiation era. Naive estimates of their production rate at a GUT phase transition suggest that today there should be roughly as many monopoles as baryons. This is a drastically unacceptable conclusion—known as the 'monopole problem'—because each monopole weighs at least 10^{16} times more than a proton. An observational limit on the monopole number density $n_{\rm M}$ arises from their dissipative effect on galactic magnetic fields; this is known as the Parker limit and yields the tiny value $n_{\rm M} < 10^{-22}$ cm^{-3}. The strongest constraint arises from the consequences of baryon catalysis if GUT-scale monopoles were captured by neutron stars, yielding $n_{\rm M} < 10^{-27}$ cm^{-3}.

Global topological defects with long-range fields, whether strings, monopoles or textures, can evolve in a scale-invariant manner. Global field correlations will be established as fast as allowed by causality, with a fixed average number of global defects in each horizon volume at any one time. Global string evolution only differs from ordinary cosmic strings in a subtle quantitative manner. However, global monopoles are dominated by long-range forces which correlate them closely with antimonopoles, leading to their rapid annihilation. For such a system,

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

we would expect the removal of all but one or two monopoles in each horizon volume. This has been verified numerically, with the number density in the matter era given by

$$n_{\rm M} = 4(\pm 1.5) d_{\rm H}^{-3}$$

where $d_{\rm H} = 3t$ is the horizon size.

The phase ordering of global textures is qualitatively similar. Once a sufficient texture winding has fallen within the horizon, the configuration reduces its gradient energy by collapsing. This unwinding process is again only limited by causality. Numerical simulations have confirmed that this is a scale-invariant process with a constant rate of texture unwindings per Hubble time and volume, which in the matter era is given by

$$\frac{{\rm d}n}{{\rm d}t} \approx 0.094 d_{\rm H}^{-4}.$$

Finally, we note the possibility of hybrid topological defects resulting from a series of phase transitions such as domain walls bounded by strings or monopoles connected by strings. Such configurations can chop themselves up, annihilate and completely disappear within a Hubble time. For example, if the flux of magnetic monopoles is temporarily confined into strings as in a superconductor, then monopole–antimonopole pairs become highly correlated; they are rapidly drawn together by the string tension and annihilate (a possible solution of the monopole problem). Alternatively, defect networks can also become 'frustrated' if there are topological constraints preventing annihilation or reconnection. A complex interconnected string network will form if there are many different string species arising from a non-Abelian symmetry breaking (e.g. $G \rightarrow Z_n$ produces n strings which interact non-trivially). In general, such configurations will dominate the universe unless their symmetry-breaking scale η is very low, but there are also circumstances under which this evolution can be scale invariant.

◇ *Quantitative string networks*

Analytic mathematical modelling, notably the 'one-scale' model, provides a fairly successful description of the gross features of an evolving string network. However, it is not adequate for the small-scale dynamics and, in any case, there are free parameters in the analytic models which must be fixed in some manner. Invariably, therefore, quantitative advances in understanding cosmic strings have relied on numerical simulations (as with other defects). Because of the complexity and non-linearity of a network, this has proved to be computationally very challenging. This is illustrated by the horizon volume string network from the radiation era shown in figure 6; a network of 'wiggly' long strings permeates throughout the universe with an accompanying population of very small loops. This wiggliness and the size of these small loops have an important impact on the astrophysical consequences of strings. Numerically, it is clear that high resolution is required, but this competes with the need for an extended dynamic range. Without an unacceptable sacrifice of this small-scale structure, string networks at present can only be evolved for a period of about 1 order of magnitude in conformal time. For global defects on a 3D grid, the problem is even more restrictive. This severe limitation is an important caveat in all the current literature on the cosmological implications of defects. ♦

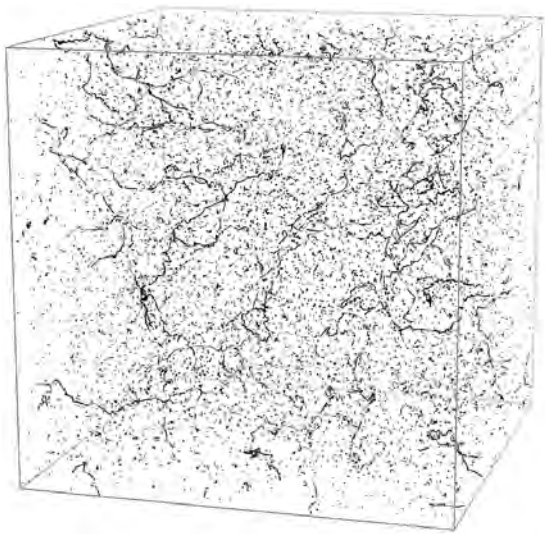

Figure 6. Horizon volume from a numerical simulation of cosmic strings during the radiation-dominated epoch.

Large-scale structure formation

Evolving superheavy defects generate complex causal gravitational fields which can induce density fluctuations in the background matter. Their scale-invariant evolution is reflected in the creation of a nearly scale-invariant or Harrison–Zeldovich spectrum of perturbations, which is very similar to that of inflationary models. For most defects, the density perturbation near the scale of the cosmological horizon remains constant:

$$\left.\frac{\delta\rho}{\rho}\right|_{\rm H} \approx \mathcal{O}(10) G\eta^2.$$

However, unlike the adiabatic (or curvature) fluctuations of standard inflation which are laid down at some early time on all relevant cosmological scales, defect perturbations are created throughout cosmic history by causal mechanisms which only operate on subhorizon scales at any one time. Ever since a phase transition carved them from the cosmological background, wherever defects exist there is always a diffuse compensating underdensity in the background which cancels out their gravitational effects beyond the horizon. In other words, defects induce isocurvature perturbations. The non-linearity of the defect source provides another possible distinction from the initially linear and Gaussian inflationary fluctuations.

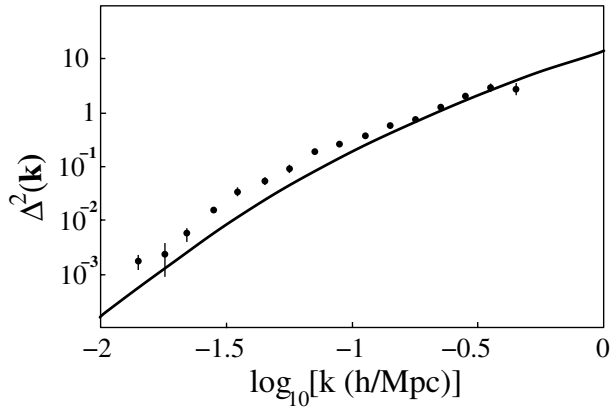

Figure 7. The power spectrum obtained for cosmic strings with cold dark matter and a significant cosmological constant $\Omega_\Lambda = 0.7$, which is normalized using large-angle CMB anisotropy (COBE). Inferred observational points from large-scale structure surveys are also included. The Hubble parameter is taken to be $h = 0.7$ and the wavenumber k is in units of h/Mpc.

In order to study the large-scale structure in a specific defect scenario we need to solve the linearized Einstein equations for a density perturbation with a source term given by the energy–momentum tensor of the evolving defect network. Given that defect simulations can only run for a short period, it is useful to characterize the scale-invariant power which they induce using unequal-time correlators. These can then be used as a scale-invariant source to greatly increase the dynamic range in a semianalytic solution of the perturbation equations. Nevertheless, this severe numerical limitation makes cosmic defect predictions considerably less reliable than corresponding results for INFLATION.

An example of the power spectrum of dark matter density perturbations produced by cosmic strings is illustrated in figure 7. This is a cold dark matter scenario with a COSMOLOGICAL CONSTANT and the string source is normalized to match the large-angle CMB anisotropies measured by COBE. The observational data points shown are the Peacock–Dodds compilation of several large-scale structure surveys. Several key features are evident, which distinguish defect models from standard inflation. Firstly, cosmic strings and other defects require considerable 'bias', that is the galaxy distribution must be more strongly clustered than the underlying dark matter. Since early non-linearity is natural in these models, it may be that this can be accommodated. Secondly, although the overall power is lower than inflation, defect models induce relatively more small-scale power. The consequence of these two features is that the shape of the defect power spectrum appears to be viable only in open models or those with a substantial cosmological constant.

Some non-Gaussianity is expected in the large-scale structure distribution induced by cosmic strings. This has been observed by studying the one-point probability density function and other statistics. However, significant non-Gaussianity is only evident on scales smaller than about $1.5(\Omega_{\rm M}h^2)^{-1}$ Mpc, that is on scales today which are non-linear in any case. The wake-like structures created by a single string are submerged among the many contributions from other strings, except paradoxically on small scales. This is because string perturbations before the equal matter–radiation transition are suppressed, so a late-time wake contribution is relatively stronger than the background.

The power spectrum induced by global monopole or texture theories appears to be less attractive than that from strings. On the one hand, in a flat matter-dominated universe ($\Omega_{\rm M} = 1$) the power spectrum has an acceptable amplitude at $8h^{-1}$ Mpc but falls away drastically on large scales. On the other hand, in an open universe or a model with a significant cosmological constant, the shape of the spectrum is improved but the overall amplitude becomes seriously deficient on all scales; biases up to an order of magnitude can be typical when normalized to large-angle CMB anisotropy. Global defect models are expected to exhibit a somewhat stronger non-Gaussian signal than strings.

Cosmic microwave sky

The greatest observational challenge to cosmic defect theories arises from the patterns they create on the cosmic microwave sky. The temperature fluctuations produced in microwave background photons travelling in a sky direction $\hat{\boldsymbol{n}}$ can be summarized by the Sachs–Wolfe formula

$$\frac{\delta T}{T} = \int h_{ij}\hat{n}^i\hat{n}^j \,\mathrm{d}t + \boldsymbol{v}\cdot\hat{\boldsymbol{n}} + \frac{4}{3}\frac{\delta\rho_\gamma}{\rho_\gamma}.$$

Here, the spacetime metric perturbation h_{ij} represents the gravitational effects of the cosmic defects, while $\boldsymbol{v}$ is the matter velocity and ρ_γ is the photon density on the surface of last scattering. For large angular scales, the first term dominates (i.e. the integrated Sachs–Wolfe effect). In standard inflation, this merely reduces to the Newtonian potential Φ on the surface of last scattering. Temperature fluctuations are mainly due to photons climbing out of the (scalar) potential wells as they decouple; these are the same wells around which large-scale structure collapses. For cosmic defects, however, large-angle CMB anisotropies are created dynamically along the whole photon trajectory by the gravitational effects of the evolving defect network. This includes additional non-scalar contributions (vector and tensor modes) which are not directly related to the induced density perturbations. These extra modes imply that defect models, when normalized by large-angle CMB observations (such as the COBE-DMR experiment), generically produce less scalar power for density fluctuations relative to inflationary models. Nevertheless, the scale invariance of defect evolution implies they produce an angular power spectrum on large scales which is nearly flat and consistent with COBE (i.e. for multipoles $\ell < 30$ in figure 8).

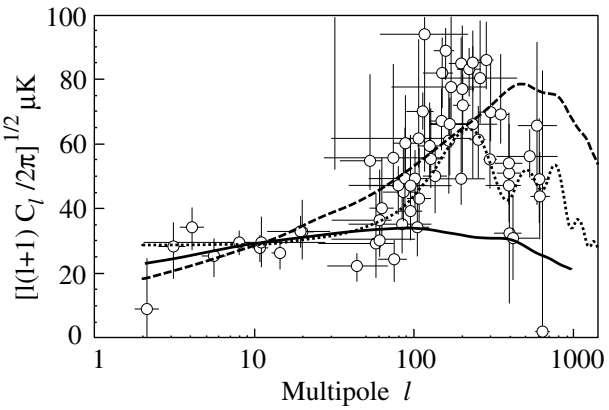

Figure 8. Angular power spectrum for cosmic microwave anisotropy from texture simulations (solid curve), a cosmic string toy model (dashed) and standard inflation (dotted), all with a Hubble parameter $h = 0.5$. The defect models are in a flat cosmology with a significant cosmological constant: textures $\Omega_\Lambda = 0.8$ and strings $\Omega_\Lambda = 0.5$. Recent CMB experimental points are included for comparison.

The additional vector and tensor modes created by defects can be illustrated by a cosmic string perturbing CMB photons when it moves across the line of sight. As the string passes in front of a distant source, the observer and source experience a small relative boost towards each other owing to the string deficit angle Δ. Thus, in the frame of the observer, the emitted light behind the string will acquire a relative Doppler blueshift, and so the string will create a line-like discontinuity in the CMB temperature pattern. Now, on large angular scales, the superposition of so many strings between the observer and the surface of last scattering means that the signal is very Gaussian. However, on very small angular scales approaching the interstring distance, this 'stringy' signature should be detectable; for example, the temperature discontinuities are inconsistent with Gaussian fluctuations on angular scales below about 2 arcmin. In a similar manner, collapsing textures or monopole pairs create hot spots in the microwave sky. Such non-Gaussian features are a distinct observational signature; they may be detectable even if the defect energy scale is below that needed for galaxy formation. A feature of defect models is that this non-Gaussian signal dies away much more slowly than inflation at high multipoles $\ell > 1000$.

On intermediate scales with multipoles $200 \leq \ell \leq 1000$, the second and third terms in the Sachs–Wolfe formula become important, that is Doppler shifts due to motion at photon decoupling and intrinsic fluctuations in the photon density ρ_γ. For these effects, defects again produce a signature quite distinct from inflation because they are isocurvature theories. In inflation, superhorizon perturbations begin to oscillate coherently as soon as they cross the horizon, providing the so-called spectrum of 'Doppler peaks' illustrated in figure 8. The primary peak due to the intrinsic photon density typically is at a multipole $\ell \approx 200$. In contrast, since cosmic defects act only on subhorizon scales, they begin to oscillate later; they are at least out of phase with adiabatic fluctuations, so the primary intrinsic peak is expected at $\ell > 300$ or greater. In fact, since defects act dynamically on scales substantially smaller than the horizon, the expected primary (scalar) peak is generally at even higher multipoles with simulations suggesting for textures $\ell \approx 350$, monopoles $\ell \approx 400$ and strings $\ell \approx 500$. Secondary peaks, if present at all, are weak because of the incoherence of the defect source. Such differences would be sufficient to distinguish cosmic defects from inflation, but the divergence is even greater when we include the integrated Sachs–Wolfe effect discussed earlier. In global defect models these dominate even at intermediate scales, so that any Doppler peaks are barely discernible as illustrated for textures in figure 8.

If present observational indications of a strong primary Doppler peak are confirmed, along with clear secondary peaks, then defect models are likely to be ruled out as the main seeds for large-scale structure formation. However, such a conclusion is subject to a number of caveats. First, the evolution of defect networks and their non-linear astrophysical effects have not been exhaustively studied, so there cannot be complete confidence in present predictions. Secondly, broken scale invariance in defect evolution may introduce features such as peaks in the angular CMB spectrum. This occurs already in cosmic string models because of the very different network densities before and after matter–radiation equality (see figure 8). Thirdly, in alternative cosmologies, the primary peak can migrate to smaller multipoles, such as in closed FRW models with a large cosmological constant. Finally, even if defects were not to be the prime cause of structure formation, they could still play a subsidiary role. This complementarity has been studied, for example, in hybrid and open inflation models. Ultimately, however, the unequivocal test for cosmic defects will be their distinct observational signature in the CMB sky on very small angular scales.

Primordial backgrounds

The scale-invariant evolution of a defect network depends on the decay of defects into a particle or radiation background. This background may well have influenced cosmic history and it may be detectable today. Supermassive cosmic strings with only local interactions oscillate relativistically and decay into gravitational radiation. The magnitude of this flat spectrum of primordial gravitational waves can be predicted from network simulations. However, millisecond pulsar timings provide an upper limit on this amplitude, since it would disturb their precise regularity. This constraint on the string energy scale, $G\mu \leq 5 \times 10^{-6}$, is quite tight but consistent with the large-angle CMB normalization. Future generations of GRAVITATIONAL WAVE detectors (such as LIGO II) will have the sensitivity to detect such a stochastic background.

Global defects decay into the massless Goldstone bosons to which they are strongly coupled. This background of Goldstone bosons, when there are too many massless degrees of freedom, can upset primordial nucleosynthesis predictions; the fraction of the energy density in the universe in Goldstone bosons at $t \sim 1$ s must be less than 5.4% for standard light element synthesis to work. This does not provide a serious constraint on GUT-scale global defects unless they are produced in many varieties.

Supermassive strings which are superconducting and carry large currents decay preferentially into electromagnetic radiation rather than gravitational waves. The resulting radiation pressure that builds up around an oscillating loop can push background plasma into a thin expanding wall. When these plasma bubble walls collide, they heat the surrounding medium and dump their energy into radiation which, in turn, can distort the Planck spectrum of the CMB. Such an explosion scenario was once proposed as a theory for large-scale structure formation, but an unacceptable CMB distortion results for sufficiently heavy strings $G\mu \geq 10^{-7}$.

Dark matter

The observable implications of defect models are not restricted exclusively to supermassive GUT-scale defects. For low or intermediate energy scales, massive relics of defect network decay can provide plausible candidates for missing dark matter. Axions are pseudo-Goldstone bosons which, in the standard thermal scenario, are predominantly produced by radiation from axion strings. Uncertain calculations of this complex process produce cosmological bounds on the axion string formation scale of approximately $\eta_a \leq 3 \times 10^{10}$ GeV. This indicates that the most likely mass range for a dark matter axion lies near $m_a \sim 0.1$ meV. Superconducting strings formed around the electroweak scale can leave behind 'vortons', that is vortex rings stabilized by their currents and charge. They may also collect charge into stable Q-ball configurations. Both vortons and Q-balls are ultra-massive cold dark matter candidates. The collapse of circular cosmic string loops could also create a distribution of primordial black holes, with a variety of observational consequences.

As noted previously, certain varieties of strings and other defects are unable to reconnect or pass through each other, so they become entangled. It is believed that the 'frustrated' defect networks that result do not evolve in a scale-invariant manner. Instead, they relax towards an equilibrium configuration which is merely stretched by the Hubble expansion and slowly comes to dominate the energy density of the universe. The network acts like an almost smooth dark matter component, but with a strange equation of state owing to the negative pressure of the defects. If the network dominates, this negative pressure causes the universe to expand faster that in the matter-dominated phase.

For non-Abelian strings in a flat cosmology ($\Omega = 1$), the universe mimics an open model ($\Omega < 1$) with the scale factor growing as $a \propto t$. Since these strings will not cluster on galaxy or cluster scales, they must not dominate well after structure formation has begun. This constraint implies that the strings must be very light forming at the electroweak scale or later, that is $\eta < 10^4$ GeV. The mean separation today of such strings would be only a few astronomical units; however, their direct detection would be extremely difficult unless they were superconducting.

Recent observational evidence favouring a flat cosmology with a low matter density has renewed interest in a non-zero cosmological constant Λ. Equally, however, frustrated defect networks could play a similar role, arguably without the severe fine-tuning problems associated with Λ. Observational tests of these models must focus on determining the equation of state $p = w\rho$ of this homogeneous background component. Frustrated strings can be expected to have $w \approx -\frac{1}{3}$, while domain walls will have $w \approx -\frac{2}{3}$, as compared with a cosmological constant with $w = -1$.

Baryogenesis

Cosmic defects can have interactions which violate baryon number B and which could, in principle, generate the matter–antimatter asymmetry of the universe (see BARYOGENESIS). Of course, B-violating interactions alone would tend to act in the opposite direction by erasing any pre-existing or primordial baryon asymmetry. However, if the B-violating interactions are also CP violating and they occur out of equilibrium (i.e. Sakharov's three criteria), then they can create a net baryon number in a baryon-symmetric universe. Several speculative defect scenarios have been proposed for this including the B- and CP-violating decay of heavy particles emitted by string cusps or small loops and B-violating scattering from superconducting strings, as well as monopole annihilation and texture collapse.

Baryon-violating processes can also occur at the electroweak phase transition. In this case, sphalerons (i.e. local texture transitions) can cause baryon number violation. However, it is difficult for these transitions to favour baryons over antibaryons in the standard electroweak model; the CP violation that does exist in the kaon system is insufficient. Instead, various extensions of the standard model, such as the minimal supersymmetric standard model (MSSM), have been studied to increase the level of CP violation. Usually, this entails mechanisms occurring on expanding bubble walls during a first-order phase transition. A small parameter range in the MSSM model remains viable for electroweak baryogenesis but this will be tested at LEP in the near future. A more detailed description of alternative models is beyond the scope of this article, but it may yet emerge that baryogenesis is the most important consequence of topological defects in cosmology.

Cosmic rays

Topological defects can produce highly energetic massive particles through their relativistic accelerations and

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

interactions. These can decay and cascade into observable cosmic rays over a broad energy range which extends to ultrahigh energies (UHEs) with $E > 10^{11}$ GeV. Most recent interest has focused on UHE cosmic rays because of the difficulty of explaining the observed events with the usual astrophysical accelerator mechanisms. Various scenarios for their generation by topological defects have been discussed in the literature including cosmic string reconnections, current loss from superconducting strings, monopole–antimonopole annihilation and hybrid networks of monopoles connected by strings. The problem faced by these models is not achieving exotic high energies but rather reaching the required flux levels. For UHE cosmic rays, both the proton attenuation length and the photon absorption length due to interactions with CMB photons are much smaller than the Hubble radius. For ordinary or superconducting cosmic strings, this cutoff is also much smaller than the mean string separation, so the cosmic ray flux they create is generically exponentially suppressed. Even if a string were nearby by chance, it would generate a highly anisotropic flux. Of course, many possibilities remain to be explored such as neutral carriers which can evade this limit.

Nevertheless, several models with GUT-scale monopoles appear to be able to generate the required flux of UHE cosmic rays. In one case, the monopoles are attached to two strings, so that they form 'beads' in a 'necklace' configuration. If the strings are light (say the electroweak scale), then the monopoles can retard the evolution such that the network evolves to a much denser state than usual with a mean interstring spacing of a few kpc. The monopoles and antimonopoles trapped on the strings continuously annihilate to produce superheavy particles which cascade into a nearly isotropic flux of cosmic rays. Another alternative is a primordial distribution of monopolonium, that is, bound states made from monopole–antimonopole pairs. These slowly decay electromagnetically and eventually annihilate. Monopolonium (or other localized defect states such as vortons) will cluster like ordinary matter, so one would expect to observe anisotropy with a peak cosmic ray flux from the Galactic center, and also from the Virgo cluster. A distinct feature of defect-generated cosmic rays is the pion dominance of hadron production, leading to a strong electromagnetic cascade; unlike most mechanisms, there are more photons than protons. For localized defects inside the photon absorption cutoff distance, this will result in a directional flux of UHE photons.

Topological defects are also invoked to account for other high-energy astrophysical phenomena which evade more conventional explanation. One example is the engine driving a γ-ray burster (GRB) which must emit in an extremely narrow beam. The cusps on superconducting strings at the GUT scale $\eta \sim 10^{14}$ GeV can achieve the beamed energy levels required and exhibit a number of the key qualitative features of GRBs.

Cosmic defects and inflation

A solution to the monopole problem was a prime motivation for inflation; any cosmic defects present before inflation would be drastically diluted by the ensuing epoch of exponential expansion. Defects and inflation, therefore, have become widely regarded as incompatible, but this is certainly not the case. Of course, light- or intermediate-scale defects can be formed at phase transitions which occur after inflation, but it is also possible to create heavy defects in significant quantities even if their energy scale is higher than the inflationary reheat temperature $\eta > T_{\rm R}$. Defect-forming phase transitions can occur during inflation or they can trigger its end, notably in hybrid inflation models. Defect networks can be created by quantum fluctuations during inflation. The quantum nucleation of symmetric defect configurations, such as circular string loops or monopole–antimonopole pairs, can also act continuously during inflation to give non-negligible final densities. A particularly interesting possibility is inflationary pre-heating which can cause non-thermal phase transitions. These can naturally give rise to superheavy defects even with $\eta > 10^{16}$ GeV. Together with inflation, cosmic defects hold out the prospect of solving a number of key cosmological enigmas.

Bibliography

The literature on topological defects in cosmology is extensive and can be approached through the references listed here. A recently updated paperback edition of a comprehensive monograph on the subject is

Torun Radio Astronomy Observatory

Torun Center for Astronomy is located at Piwnice, 15 km north of Torun, Poland. A part of the Faculty of Physics and Astronomy of the Nicolaus Copernicus University, it was created by the union of Torun Radio Astronomy Observatory (TRAO) and the Institute of Astronomy on 1 January 1997.

Since 1981 the observatory has been part of a worldwide network of radio observatories participating in VLBI (very long baseline interferometry). With the new 32 m telescope and modern sophisticated instrumentation, Torun station is the only VLBI site in eastern Europe. It recently became a member of the European Pulsar Network (EuroToP).

Research concentrates on observations and theoretical interpretation of physical processes in radio galaxies and quasars, the timing of pulsars, the search for new planetary systems and solar system studies. The development of instrumentation for radioastronomy (ultra low-noise receivers, spectrometers, frequency converters, digital electronics, control systems) is also important.

Townes, Charles Hard (1915–)

Physicist, born in Greenville, SC, Nobel prizewinner for physics in 1964 'for fundamental work in the field of quantum electronics, which has led to the construction of oscillators and amplifiers based on the maser-laser principle'. Worked at Bell Telephone Laboratories and Columbia University on microwave spectroscopy to study the structure of molecules, atoms and nuclei. Conceived the idea of a device for microwave amplification by stimulated emission of radiation, coining the word 'maser' from the acronym. Became professor of physics at the Massachusetts Institute of Technology, and then at the University of California. He used the maser device to make sensitive amplifiers for radioastronomy and predicted the existence of the OH line in molecules of interstellar space.

TRACE (Transition Region and Coronal Explorer)

The Transition Region and Coronal Explorer (TRACE) is a NASA Small-Explorer (SMEX) satellite developed to study the impact of magnetic fields on the solar outer atmosphere. The instrument observes the solar surface (SOLAR PHOTOSPHERE) and the hotter overlying domains (TRANSITION REGION and CORONA) with an angular resolution of 1 arcsec, equivalent to 725 km on the Sun, an average cadence of about 30 s, and a field of view of 512 by 512 arcsec (covering one-tenth of the solar disk). The TRACE observatory was launched on 2 April 1998 from Vandenberg Air Force Base on a Pegasus XL launch vehicle built by Orbital Sciences Corporation. The spacecraft is in a polar orbit roughly over the day–night terminator. This Sun-synchronous orbit allows TRACE to see the Sun without interruptions for a period of approximately nine months of the year, while there are some ECLIPSES of the Sun by the Earth during the other three months.

The main scientific objective of the TRACE mission is to enhance our understanding of the dynamic, hot solar outer atmosphere. To achieve this goal, the instrument is used to:

- Study how the SOLAR MAGNETIC FIELD structures the outer atmosphere, from the photospheric surface to the high corona, covering a temperature range from 5000 up to several million degrees.
- Observe how the magnetic fields evolve from their emergence onto the solar surface up to their disappearance, observing both the gradual dispersal and decay of the field and the occasional instabilities that occur (in FLARES).
- Investigate the entire range of scales from the instrumental resolution (725 km) up to the global field, and the way in which these scales influence each other.

To achieve these objectives the TRACE instrument uses a 30 cm aperture CASSEGRAIN TELESCOPE with normal-incidence optics to image wavelengths at visible, ultraviolet (UV) and extreme-ultraviolet (EUV) wavelengths. The instrument was developed by a team composed of the Lockheed-Martin Advanced Technology Center, the Smithsonian Astrophysical Observatory, NASA/Goddard Space Flight Center and Montana State University.

Instrument description

The TRACE telescope is divided into four quadrants. Each quadrant has an optimized optical coating on the primary and secondary mirrors as well as special filters for the selection of the wavelength to be observed. The appropriate mirror segment is selected with a rotating quadrant selector just behind the front window. The EUV quadrants are coated with multilayers, i.e. multiple layers of very thin coatings that allow the use of normal-incidence optics to observe the EUV wavelengths. These multilayer coatings were of the highest reflectivity and narrowest bandpass ever deployed in space at the time of launch. The UV quadrant uses a narrowband multilayer on the primary mirror (optimized for 1550 Å) and an aluminum coating on the secondary to provide for a capability to image a wide range of wavelengths in the UV and visible (see table 1). A set of filter wheels in front of the detector provides the final selection of the desired wavelengths. The image is recorded on a lumogen-coated charge-coupled display (CCD) to make it sensitive to both UV and EUV wavelengths. Typical observing programs cycle through multiple wavelengths to observe different temperature domains in the solar atmosphere.

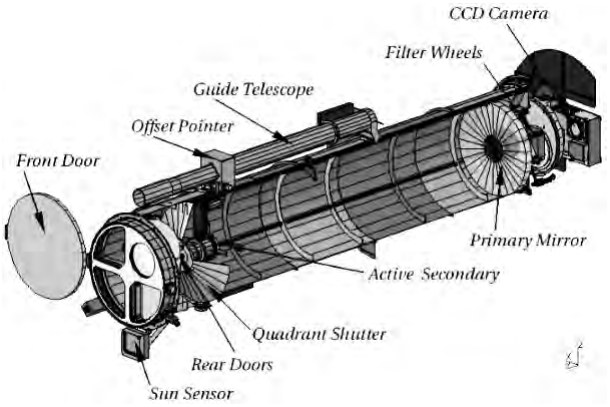

Figure 1. The TRACE instrument.

Table 1. Wavelengths observed by TRACE.

Wavelength (Å)	Emission	Temperature (kK)
173	Fe IX/X	160–2000
195	Fe XII	500–2000
284	Fe XV	1250–4000
1216	H I Ly α	10–30
1550	C IV	60–250
1600	UV cont, C I, Fe II	4–10
1700	Continuum	4–10
5000	White light	4–6.4

At the time of launch, the TRACE telescope had the highest spatial resolution of any space-borne imaging solar telescope, with a angular resolution of 1 arcsec or 725 km. The CCD detector (with 0.5 arcsec pixels) is a 1024×1024 array, with a field of view of 8.5×8.5 arcmin (equivalent to 6.2×6.2 Mm at the solar disk center).

The instrument maintains pointing to an accuracy of 0.1 arcsec by a combination of gyrostabilization of the spacecraft with further stabilization achieved by moving the secondary mirror in response to a signal from an external GUIDE TELESCOPE. The satellite points to various locations on the Sun directed by the guide-telescope signal, in which rotating wedge prisms are used to deflect the optical axis of the telescope in the desired direction within a cone of $\pm 1^\circ$ away from the center of the disk.

The onboard computer system is responsible for various housekeeping functions, JPEG data compression and limited scientific image processing prior to downlinking the signal. Normally six downlinks occur daily at Wallops Flight Facility, Maryland, USA; Poker Flat, Alaska, USA and McMurdo Station, Antarctica. This combination of operations, data compression and creative planning techniques allow TRACE to record one full image roughly every minute when operating in a continuous mode, resulting in a data rate of ≈ 0.5 Gbyte day^{-1}.

Operations and data archive

Standard science operations are executed from the TRACE Experiment Operations Facility (EOF) at Goddard Space Flight Center. Operations personnel closely coordinate with other observatories, particularly with the Solar and Heliospheric Observatory (SOHO). In addition to general operations in response to solar conditions and requests from other observatories, TRACE covers the entire Sun to construct a full-disk mosaic of the central meridian at least every other day.

During the first nine months of operations, up to the beginning of the first eclipse season, TRACE acquired nearly a million exposures, running at an average cadence of three images per minute. The TRACE project has a policy of making all data available to colleagues and the general public within at most a few days of the observation.

Science highlights

The TRACE images present a view of the solar outer atmosphere not anticipated prior to launch. Many of these observations are likely to take some time yet to be properly interpreted. Some early highlights are discussed below:

Perhaps most exciting is the level of structural detail and the short evolutionary timescales that are apparent in TRACE image sequences. The smallest features are still unresolved at 1 arcsec resolution. In fact, entire magnetic loops in the corona are seen to have a cross section at the instrumental resolution, suggesting that the actual widths of such loops are smaller still. Movies show significant restructuring of the solar corona down to temporal cadences of some 10 s.

The solar corona shows a wide range of loops, ranging from about the instrumental resolution up to hundreds of thousands of kilometers. These loops connect either opposite polarities in photospheric regions that emerged together or reconnect to form connections between magnetic flux concentrations that emerged at separate times and locations. Over large bipolar active regions in the photosphere, the corona shows the following thermal pattern. Over the inner parts of the region near the polarity inversion line, the corona is relatively hot with temperatures typically of 3 to 5 million degrees, observable by the Yohkoh/SXT instrument. Surrounding that inner core is an ensemble of loops with substantially lower temperatures, visible to TRACE. The material in these loops, many of which have temperatures throughout their interior of near 1 million degrees, is strongly stratified under the influence of gravity, leading to emission primarily in their lower segments.

One particularly interesting feature in TRACE observations is the so-called moss. This moss is a low-lying, bright emission pattern with many dark inclusions, overlying the inner parts of active regions, underneath the hot 3–5 million degree corona. The moss has been identified as the upper transition region between the CHROMOSPHERE and the corona, through which energy is transported primarily by thermal conduction. As the temperature gradient is very steep, the layer of emission is rather thin. Material at chromospheric temperatures is injected into this height range from below, by an as yet unidentified mechanism, causing rapidly evolving dark intrusions in the moss pattern. On a few occasions, TRACE movies have shown patches of the moss evolving in a manner akin to a prairie fire following a flare, reflecting the thermal evolution of the loops higher up in the corona.

The TRACE temporal and spatial resolution has allowed solar physicists to directly observe for the first time oscillations in CORONAL LOOPS. These oscillations are almost invariably observed in the lower segments of loops ending in sunspots. Large-amplitude transverse oscillations are frequently observed after solar flares, when the associated blast wave excites such oscillations.

Transit

The passage of a celestial body across the disk of a much larger one. The term is applied most commonly to passages of Mercury and Venus across the face of the Sun. Such transits were first reliably predicted by Johannes Kepler, in his *Rudolphine Tables* of planetary motion. From these predictions Pierre Gassendi became the first to observe a transit of Mercury, in 1631; eight years later Jeremiah Horrocks, also using Kepler's tables, made the first observation of a transit of Venus. These two planets are seen in transit when near one of their nodes at inferior conjunction. Mercury is at its ascending node in November, and its descending node in May; these occasions coincide with inferior conjunction at intervals of 7, 13 and 46 years (ascending node) and 13 and 46 years (descending node). Transits of Venus are much rarer. They can happen near June 7 (ascending node) or December 8 (ascending node), and recur in pairs, 8 years apart, at intervals of $105\frac{1}{2}$ years and $121\frac{1}{2}$ years. The next pair will be on 2004 June 8 and 2012 June 5/6; these will be only the fifth and sixth transits since the one Horrocks observed in 1639. From the eighteenth century transits afforded an important means of determining the scale of the solar system. Its relative proportions were known from Kepler's laws. Accurate timings of transits from widely separated locations on the Earth's surface provided a trigonometric fix. Early attempts to do this for Venus were frustrated by the refraction of sunlight through the planet's atmosphere, which makes the planet appear smaller than usual, and by the black drop effect.

The major satellites of planets may be seen to transit the face of their parent planet. The four largest satellites of Jupiter, known as the Galilean satellites, frequently transit the planet's disk; the larger inner satellites of Saturn may also be observed in transit. A satellite's shadow is sometimes visible crossing the planetary disk in a *shadow transit*. The term 'transit' is also used by planetary observers to indicate the passage of an atmospheric or surface feature across a planet's central meridian—the imaginary line that bisects its visible disk, from the north pole to the south pole. Timing such transits provides a means of determining a planet's rotation period.

Transition Region Flows

Ultraviolet emission lines emitted from the SOLAR TRANSITION REGION are often shifted from their expected rest wavelengths. Shifts of spectral lines are due to the so-called DOPPLER EFFECT, where the source of emission is moving either away from or towards the observer, causing a change in the apparent wavelength. The shifted emission lines are most often interpreted as a flow of plasma along magnetic field lines or loops with velocities varying from a few $\mathrm{km\,s^{-1}}$ to several hundreds of $\mathrm{km\,s^{-1}}$. Flows observed in the transition region can be divided into three main groups: steady flows with relatively small velocities observed in the quiet Sun, short-lived high-velocity events in the quiet Sun and high-velocity (often supersonic) flows connected to SOLAR ACTIVE REGIONS. The latter includes flows related to flaring activity and mass ejections. The different types of flow are discussed below but one should keep in mind that plasma flow is not the only explanation for the Doppler-shifted emission lines. Model calculations suggest that waves propagating through the solar atmosphere can also produce line shifts and complex line profiles.

Systematic flows in the quiet Sun

One of the most puzzling problems in solar physics is the apparent net redshift of emission lines in the solar transition region. In recent decades, this phenomenon has been observed with several UV instruments with different spatial resolutions. For the Sun, the typical value of the average downflow velocity, derived from the C IV resonance lines at 1550 Å, is 5–10 km $\mathrm{s^{-1}}$. The C IV lines are formed at temperatures around 10^5 K. Measurements of the variation of the flow with temperature are somewhat ambiguous, however.

In earlier investigations the magnitude of the redshift has been found to increase with temperature, reaching a maximum at $T = 10^5$ K, and then to decrease sharply toward higher temperatures (2.5×10^5 K). These results have been used extensively in models trying to explain the mechanisms behind this phenomenon. Recent observations from SOHO have extended the observable temperature range and suggest that the average redshift persists to higher temperatures than in previous investigations. Shifts in the range 10–16 $\mathrm{km\,s^{-1}}$ are observed in lines formed at $T = (1.3$–$2.5) \times 10^5$ K. Even upper transition region and coronal lines (O VI, Ne VIII and Mg X) show systematic redshifts in the quiet Sun corresponding to velocities around +5 $\mathrm{km\,s^{-1}}$. These results have introduced new constraints on models of the redshifts in the solar atmosphere. In coronal holes there is evidence for a small net blueshift in the upper transition region, while at lower temperatures the lines still show a net redshift.

An interesting feature of the transition region is that the average redshifted emissions appear to be a persistent phenomenon in both quiet and active regions. The estimated downward mass flux around $T = 10^5$ K is sufficient to empty the corona in a few minutes. It therefore seems likely that upflows also exist that could balance the observed downflow unless the Doppler shifts are caused by waves propagating through the transition region. Both downflows and upflows may occur where, for some reason, the downflowing plasma is slightly brighter than the upflowing plasma.

Several hypotheses to explain the redshifted emission have been proposed so far and they include: the return of spicular material; siphon flows in coronal loops; nanoflares followed by downward propagating acoustic waves; a different temporal duration of upflows and downflows; and asymmetric heating of coronal loops. None of them has been found to be entirely satisfactory. Thus, other mechanisms should still be considered to explain the observed redshifts at higher temperatures.

Detailed studies of the redshifted emission observed on the Sun also are important for the understanding of similar observations of stellar spectra. Systematic redshifts have also been observed in spectra of late-type stars, first with the INTERNATIONAL ULTRAVIOLET EXPLORER (IUE) and recently by the HUBBLE SPACE TELESCOPE. Below temperatures of about 1.6×10^5 K, the line redshifts of the Sun, α Cen A, α Cen B and Procyon are all very similar. However, at higher temperatures both α Cen A and α Cen B suggest drop-offs in redshifts similar to that suggested by the solar data. In comparison, no drop-off in the redshifts was found in the spectra from Procyon, which is a hotter and somewhat more active star than the Sun.

High-velocity events

High-velocity events in the solar transition region were first observed in UV spectra obtained with the Naval Research Laboratory's High Resolution Telescope and Spectrograph (HRTS). The strength of the HRTS instrument is its high spatial, spectral and time resolution combined with the extensive wavelength and angular coverage. This makes it well suited for studies of fine structure and mass flows in the upper solar atmosphere and led to the discovery of short-lived transient events with high velocities, so-called explosive events (see TRANSITION EVENTS: EXPLOSIVE EVENTS). Explosive events are found to be short-lived (60 s), small-scale (1500 km) high-velocity flows that occur frequently, with a birthrate of $\sim$ 600 $\mathrm{s^{-1}}$, over the entire surface of the Sun. The observed Doppler shifts correspond to line-of-sight velocities of typically 150 $\mathrm{km\,s^{-1}}$ towards and away from the observer. Many observations suggest that explosive events are bi-directional jets and that they are evidence of MAGNETIC RECONNECTION above the solar surface. However, other mechanisms are also possible, including episodic nonlinear MHD disturbances produced by nano-flares that will introduce particle motions leading to broad line profiles as observed in explosive events. Flows with opposite directions within unresolved loop structures should also be considered since many explosive events show multiple line components.

The concept of multiple flows is another interesting feature seen in the HRTS data and they are most common

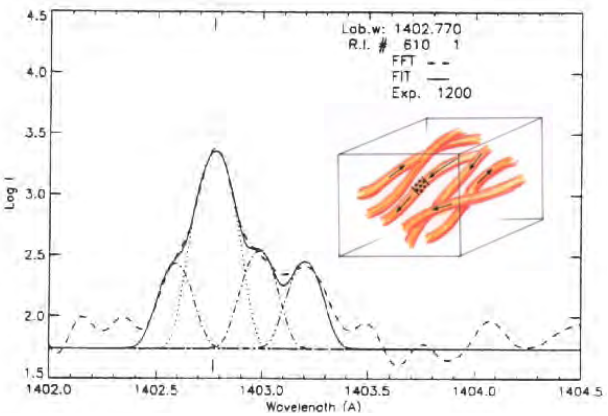

Figure 1. A complex Si IV 1402 Å profile observed with the HRTS instrument. The dashed curve shows the raw data. The profiles have been fitted with Gaussian line components (solid curve) and each separate line component is indicated. The inser shows a sketch of a possible explanation of the observed profiles.

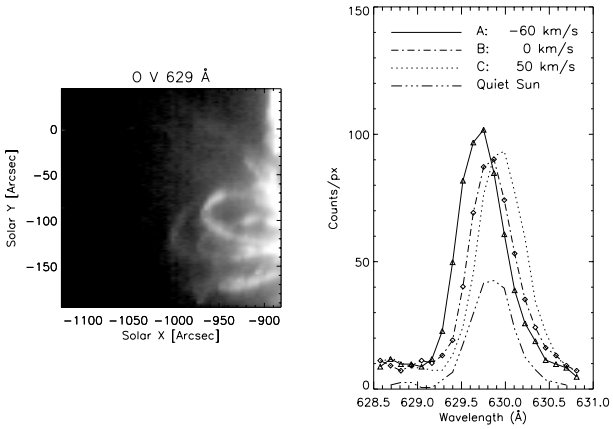

Figure 2. An active-region loop system above the east solar limb observed in O V 629 Å by the Coronal Diagnostic Spectrometer (CDS). The line profiles from three different spatial locations (A, B and C) are displayed in the right panel together with a reference profile representing a typical quiet Sun profile at rest wavelength.

above active regions but are also present in the quiet Sun. An example of a complex Si IV 1402 Å profile is shown in figure 1 and was recorded during a rocket flight in 1978. The dashed curves are the original observations while the solid curve represents the spectrum derived from Gaussian fits to the profile components. The shift of the fitted line components corresponds to velocities of -40, 8, 75 and 105 km s^{-1}. Thus, both subsonic and supersonic velocities may coexist within the same 1 arcsec^2 resolution element, suggesting the presence of an extremely structured transition region. To explain the complex profiles with siphon flows would require several loop strands each with their own flow. An alternative explanation may be episodic nonlinear MHD disturbances as mentioned above.

Flows in active-region loops

Observations of active regions above the solar limb reveal individual loops that are often too faint to be observed against the brighter disk. Observations made with the Coronal Diagnostic Spectrometer (CDS) on SOHO show clear evidence of strong dynamical activity within individual loops. The CDS spectrometer builds up images of solar features in a series of spectral lines. Each image retains detailed spectral information and can be used to give maps of total emission, velocities, line widths, plasma densities etc. A monochromatic image of an active-region loop system above the east limb observed in O V 629 Å ($T \sim 250\,000$ K) is shown in figure 2. The field of view of the image is 240 × 240 arsec^2. For each single pixel element in the CDS raster images one can extract the entire line profile to derive line-of-sight velocities. Three spatial positions have been marked and the line profiles from these locations are displayed in the panel to the right.

The line shift at location A corresponds to a gas motion toward the observer with a velocity of 60 km s^{-1} (216 000 km h^{-1}). In the other leg of the loop, at location B, there is surprisingly no shift, and hence no motion. Location C belongs to a different loop where we again observe clear shifts, corresponding to motions of 50 km s^{-1} (180 000 km h^{-1}) in the opposite direction, away from the observer.

The fact that one observes a large Doppler shift in only one part of the loop is intriguing. If gas is moving up one leg and coming down the other one would expect to see the flows continue in the other leg. This is not always the case; thus one needs to consider other possible mechanisms causing the Doppler shifts, e.g. Alfvén waves or magnetosonic waves running along the magnetic field in the loop. However, flows seem to be a general property of active-region loops as observed at transition region temperatures. Typical values correspond to velocities of the order ±50–100 km s^{-1}. In the line formed at coronal temperatures the shifts are much smaller, often not detectable. Thus, the high shifts seem to be a phenomenon occurring at transition region temperatures.

While the hot coronal loops develop more slowly, recent observations made with CDS, and in particular TRACE (TRANSITION REGION AND CORONAL EXPLORER), demonstrate that the large cool loops from the transition region are very dynamic (see figure 3). It is clear that the cool loops change on a timescale shorter than 1 min. This should be compared with the 17 min it takes to complete the monochromatic image in figure 2. Thus, the dynamic state of the loop changes significantly over the time it takes to build up a raster image with any spectrometers. The time sequence in figure 3 also suggests substantial movements of emitting plasma. Blobs of emission move along the loop, sometimes from one footpoint to the other. At other times gas appears to drain down from the top of the loop towards the footpoints. In some cases the loop seems to be filled from one footpoint to the other as is illustrated in

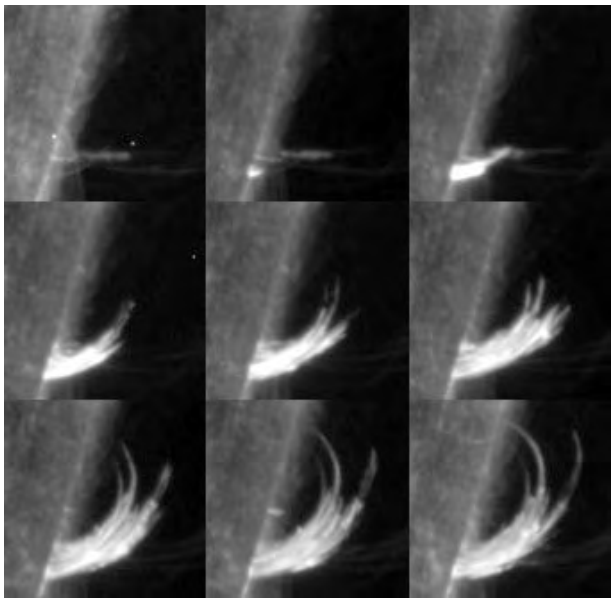

Figure 3. Active-region loops observed with Transition Region and Coronal Explorer (TRACE) illustrating the dynamic behavior of the plasma in the transition region. The images run with time from the start in the upper left corner and to the right in every horizontal row. Time between images is about 30 s.

figure 3. The observations were made with the TRACE and show active-region loops on the limb. The emission comes mainly from C IV formed at 10^5 K and the time cadence between the images is 30 s. The field of view is 55 $\times$ 55 arcsec. The images run with time from the start in the upper left corner and to the right in every horizontal row. In just about 3 min a cluster of thin loops are filled from the onset at the lower footpoint almost to the other loop footpoint. Again, even if flows may be a plausible explanation we cannot rule out other mechanisms such as waves.

Flows above sunspots

The spectrometers CDS and SUMER on SOHO have been used to observe the spatial distribution of line emission and line-of-sight velocities above a number of active regions that all included a single sunspot or a sunspot group. All the active regions show enhanced EUV line emission in the transition region, the emission is distributed non-uniformly and is located both inside and outside the sunspots. Both up- and downflows are observed in the regions often with velocities higher than ± 30 km s^{-1} .

The spatial extent of both emission features and flow regions increases with increasing temperature within the transition region. The observations show a marked difference between the transition region and the low corona, regarding both the spatial distribution of the line emission and the line-of-sight velocity. Two out of three sunspot regions show enhanced line emission above the sunspot, i.e. sunspot plumes. The line-of-sight velocity in sunspot plumes is directed away from the observer and is found to increase with increasing line formation temperature; it reaches a maximum value up to 40 km s^{-1} near temperatures of (3–4) $\times 10^5$ K, then decreases abruptly.

Flows related to flares

Mass motions in SOLAR FLARES have been extensively studied in the lower chromosphere and in the corona. However, there are only a few measurements of mass flows in the solar transition region during flares. Redshifts in flare spectra from OSO 8 and Skylab suggested downward motion of 30–50 km s^{-1}. However, coronal emission lines appeared to show a blueshifted component of emission together with a strong stationary component based on observations from the Solar Maximum Mission (SMM). Upflows reaching velocities of 200 km s^{-1} during the impulsive phase of the flare have been observed in the coronal line Fe XXI 1354 Å. Similar upflows (200–300 km s^{-1}) were also observed with the Bent Crystal Spectrometer on SMM. Based on a large survey of more than 200 flares observed in soft x-rays with Yohkoh, the centroids of flare profiles were found to be blueshifted with an average velocity of 58 km s^{-1} during the early impulsive phase. However, the blueshifted components reached velocities up to 800 km s^{-1}.

Considerable improvement in stellar flare observations followed the deployment of the Hubble Space Telescope (HST), in particular from observations with the Goddard High Resolution Spectrograph (GHRS). Doppler shifts during stellar flares have been detected with velocities as large as 1800 km s^{-1} away from the observer.

Transition Region Models

The SOLAR TRANSITION REGION comprises the PLASMA between the CHROMOSPHERE and the CORONA. In both of these regions the temperature is fairly uniform. The transition region, by contrast, is believed to be characterized by a very steep temperature rise from a chromospheric temperature of slightly less than 10^4 K to coronal temperatures on the order of 10^6 K. The goal of modeling the transition region is to construct physical models, i.e. the run of density, temperature, velocity with height, such that the physical processes dominating the region are illuminated and the important aspects of the line emission from the transition region may be reproduced. As hydrogen is fully ionized and therefore cannot radiate in the transition region, radiative emission is mainly in the form of the resonance lines of (multiply) ionized metals; the ions of carbon, silicon, nitrogen, oxygen, neons and iron dominate.

Basic principles

The outer layers of the Sun require a mechanical, as opposed to radiative, heat input in order to support energy losses through radiation, heat conduction, and SOLAR WIND ACCELERATION. Much can be learned about the outer layers of the Sun, and in particular about transition region structure, by considering how this dissipated mechanical energy flux is disposed of. In the chromosphere, where the density is comparatively large, a dissipated energy flux can easily be radiated away by slightly raising the temperature that is required to maintain radiative equilibrium. In the less dense transition region and in the corona other loss mechanisms dominate: assume for a moment a sun without a corona and consider the radiative losses as a function of height. The scale height (the height over which the plasma pressure drops by a factor of e; $H_\mathrm{p} = kT/mg$) in the chromosphere is on the order of a few hundred kilometers. As we proceed outward from the photosphere the gas becomes rapidly less dense and as we approach the upper chromosphere, say 1.5–2 Mm or roughly 10 scale heights above the photosphere, the radiative losses which scale with the product of the electron and total hydrogen density ($n_\mathrm{e} n_\mathrm{H}$) decrease exponentially. Any excess mechanical energy flux dissipation will therefore necessarily overwhelm the plasma's ability to radiate and its temperature will rise dramatically: a corona will form. The temperature of the material will continue to rise until energy losses balance the excess mechanical energy flux dissipation. In the corona radiative losses remain ineffective and there are two potential energy sinks: through inward heat conduction (with subsequent radiative losses from the upper chromosphere) and, in magnetically open regions, through the acceleration of the solar wind. The temperature sensitivity of these processes will almost invariably ensure that the coronal temperature is on the order of 10^6 K and that the transition region has a rapid temperature rise, from 10^4 K to 10^6 K in roughly 1 Mm, almost regardless of the form or magnitude of the CORONAL HEATING MECHANISM.

Spatial structure

The corona receives an energy flux of approximately 500 W m^{-2} in magnetically open regions and perhaps 2–20 times that in closed and active regions respectively. Let us consider the temperature structure that arises in a magnetically closed region. We assume that all the energy deposited in the corona is conducted back towards the chromosphere through the transition region, and that radiative losses are not energetically important in the corona or transition region. The temperature structure in the transition region is then given by solving the energy equation

$$F_\mathrm{c} = \kappa_0 T^{5/2} \frac{\mathrm{d}T}{\mathrm{d}z} \approx F_\mathrm{m0} \qquad (1)$$

where F_m0 is a constant that represents the mechanical energy flux dissipated in the corona. As an example let us set $F_\mathrm{m0} = 100$ W m^{-2}, with $\kappa_0 = 10^{-11}$ W m^{-1} K$^{-7/2}$; this results in a temperature gradient $\mathrm{d}T/\mathrm{d}r \approx 3$ K m^{-1} at 10^5 K or, equivalently, a temperature scale height of $H_\mathrm{T} \approx 35$ km. The temperature scale height is much smaller than the transition region pressure scale height $H_\mathrm{p} \approx 5000$ km. Thus, the temperature gradient is expected to be steep while the pressure will be approximately constant across the transition region, which only extends some 1 Mm.

A typical CORONAL LOOP has length on the order of 10–30 Mm while the chromosphere's vertical extent is roughly 2 Mm. The transition region in the loop will be in a location such that the divergence of the conductive flux flowing from the corona balances the radiative losses at the top of the chromosphere. If the energy flux dissipated in the corona increases, the conductive flux received by the chromosphere will also increase: chromospheric material will heat up and 'evaporate' into the corona and the transition region will move down towards a higher pressure. The opposite phenomenon will occur if less energy is deposited in the corona: the material at the top of the chromosphere will radiate more energy than can be replaced by conduction and the material will cool, moving the transition region upward until energy balance is established again. Since the intensity of EUV emission lines formed in the transition region scales with the density squared we expect that the most vigorously heated loops will be the densest and therefore radiate most intensely. In figure 1 we illustrate the effect of varying the energy input into a coronal loop. The temperature structures of several models are plotted showing the variation of the location of the transition region and the transition region temperature gradient. The chromospheric scale height is on the order of 200 km in these models so the density (pressure) at the base of the transition region varies by a factor of 20 between the model with $F_\mathrm{m0} = 100$ W m^{-2} and $F_\mathrm{m0} = 3000$ W m^{-2}. The intensity of the transition region line C IV 1548 Å which is formed at 10^5 K varies from 0.5 W m^{-2} sr^{-1} to 11 W m^{-2} sr^{-1} in the same models; some of the increase expected because of the density is canceled by the increased temperature gradient which reduces the extent of the line-forming region.
